ABSTRACT
Kernel PCA has received a lot of attention over the past years and showed useful for many image processing problems. In this paper we analyse the issue of normalization in Kernel PCA for the pre-image problem. We present a geometric interpretation of the normalization process for the gaussian kernel. As a consequence, we could formulate a correct normalization criterion in centered feature space. Furthermore, we show how the proposed normalization criterion improves previous pre-image methods for the task of image denoising.

Index Terms— Kernel PCA, Out-of-Sample, Image Denoising

1. INTRODUCTION

1.1. Kernel Methods
Kernel methods are a class of powerful techniques that have been widely used in the field of pattern recognition, with applications ranging from clustering, classification and recognition to image denoising, signal reconstruction and shape priors [1, 2]. The key idea of these methods is to map the training data (such as vectors, images, graphs, . . .) from the input space $\chi$ into a high-dimensional Hilbert space $H$ that is better suited for analysis than the original input space. To do so, a mapping, denoted $\Phi: \chi \mapsto H$, is implicitly defined by the property $\langle \Phi(s_i), \Phi(s_j) \rangle_H = W_{i,j}$, where $W_{i,j} = w(s_i, s_j)$ gives the inner product $\langle .. \rangle_H$ between two points in the feature space and is a measure for similarity. In practice, the mapping does not have to be computed explicitly as most techniques only require the computation of dot products that can be evaluated directly using the kernel $w(., .)$. This is called the kernel trick.

The high-dimensional, possibly infinite-dimensional, space $H$ is better suited for analysis because data may then be processed by linear methods such as Principal Component Analysis (PCA). PCA is a widely used method to compute second order statistics in data sets. The principal axis found by PCA reflect the main modes of variation present in the data set. Kernel PCA refers to the generalization of linear PCA to its nonlinear counterpart. It was introduced by Schoelkopf [2] and is one amongst the most prominent kernel methods. It has received a lot of attention in the data analysis and computer vision community. Using this methodology, it is possible to extract efficiently meaningful structure present in non-linear data, thereby significantly improving PCA results [3, 4, 5, 6].

In general, the mapping $\Phi$, also referred to as an embedding, is only known over the training set. The extension of the mapping to new input points is of primary importance for kernel based methods whose success depends crucially on the “accuracy” of the extension. This problem, referred to as the out-of-sample problem, is often solved using the popular Nyström extension method [6, 7, 8]. In addition, the reverse mapping from the feature space back to the input space is often required. After operations are performed in feature space (these operations often necessitate the extension of the mapping), corresponding data points in input space often needs to be estimated. This problem is known as the pre-image problem.

The pre-image problem has received a lot of attention in kernel methods [6, 3, 5, 4]. Recently, Arias and coworkers [6] have shown its close connection with the out-of-sample problem. They also carefully considered the issue of normalization in feature space, thereby improving the “accuracy” of the out-of-sample extension and the pre-image estimation.

1.2. Contributions
Kernel PCA is achieved by applying a principal component analysis on the mapped training samples. PCA computes an eigen-decomposition of a kernel matrix deduced from the adjacency matrix $W$. Before applying PCA, the data is centered at the origin. In Kernel PCA the mean of the mapped input points is not known. Therefore, to simplify, one often assumes that the mapped training points $\Phi(s_i)$ are already centered in the feature space $H$ and incorrectly diagonalize the adjacency matrix $W$ [6, 4]. Although simpler to understand, the resulting presentation of kernel methods misses some important points.

Our analysis of the kernel PCA methods studies in detail the centering of the data and underlines some important properties of the geometry of the mapped data induced by the kernel. We focus on the Gaussian kernel $w(s_i, s_j) =$
Kernel PCA

Let \( \{ s_1, \ldots, s_p \} \) be a set of training data in the input space \( \chi \). Kernel PCA computes the principal components of mapped features in the feature space \( \mathbb{H} \). The mapping can be explicitly computed by the eigen-decomposition of a centered kernel matrix deduced from the adjacency matrix \( W \). The coefficients of the adjacency matrix \( W \) are a measure of similarity between samples. Typically, the kernel function \( w(\cdot, \cdot) \) is a decreasing function of the distance \( d_{ij} \) between training points \( s_i \) and \( s_j \).

In this work, we focus on the Gaussian kernel. The Gaussian kernel has the important property of implicitly mapping the training points onto the unit sphere of \( \mathbb{H} \), since \( \| \Phi^*(s_i) \|^2 = \langle \Phi^*(s_i), \Phi^*(s_i) \rangle_{\mathbb{H}} = W_{i,i} = 1 \). This important normalization property has been extensively used by Arias and coworkers [6] to improve the “accuracy” of previous pre-image methods [3, 5, 4]. In this work, we state the Kernel PCA methodology in centered space and shows that a finer degree of normalization can be achieved by considering the geometry of the mapped features.

Let \( \Phi^* = \frac{1}{p} \sum_{s_i \in \Gamma} \Phi^*(s_i) \) and \( \Phi^* \) denote the centered mapping, i.e. \( \Phi^*(s_i) = \Phi^*(s_i) - \Phi^* \). The mapping \( \Phi^* \) can be computed by the eigen-decomposition of a centered kernel \( P^* \) [2]:

\[
P^* = HH^T = \Psi^* \Lambda^* \Psi^* T = \Psi^* \sqrt{\Lambda^*} \left( \Psi^* \sqrt{\Lambda^*} \right)^T,
\]

where \( H \) is the centering matrix \( H = \mathbf{I} - \frac{1}{p} \mathbf{1}_p \mathbf{1}_p^T \) and \( \Lambda^* = \text{diag} \{ \lambda_1^*, \ldots, \lambda_p^* \} \) with \( \lambda_i^* \geq \cdots \geq \lambda_{p-1}^* > \lambda_p^* = 0 \). We denote \( \Lambda = \text{diag} \{ \lambda_1, \ldots, \lambda_{p-1} \} \) and \( \Psi = (\Psi_1, \ldots, \Psi_{p-1}) \), the mapping is obtained as:

\[
\Phi^*: \chi \rightarrow \mathbb{R}^{p-1}, \quad \Phi^*(s_i) = \sqrt{\Lambda^*} \Psi^* T e_i^*.
\]

The canonical basis \( \{ e_1^*, \ldots, e_{p-1}^* \} \) of \( \mathbb{R}^{p-1} \), defined formally by \( e_k^* = \frac{1}{\sqrt{\lambda_k}} \sum_{s_i \in \Gamma} \Psi^*(s_i) \Phi^*(s_i) \), captures the variability of the point cloud of training samples. Projection of a new test point \( s \in \chi \) onto the \( k \)-th canonical vector \( e_k^* \) in the feature space can be shown to be:

\[
\beta_k(s) = \langle e_k^*, \Phi^*(s) \rangle = e_k^T \frac{1}{\sqrt{\lambda}} \hat{\Psi}^T p_s^* \tag{2}
\]

where \( p_s^* = H(w_s - \frac{1}{p} W \mathbf{1}_p)(s, s) \). \( \beta_k(s) \) is the extended mapping in centered feature space computed by centering the kernel vector \( w_s \). This way of extending embedding coordinates to new test points has been used implicitly [3, 5, 4] or explicitly [6] in Kernel methods [10]. Projecting a new test point \( s \in \chi \) onto the subspace spanned by the first \( m^* \) vectors \( \{ e_1^*, \ldots, e_{m^*} \} \) (i.e. \( P_{m^*}^* (\Phi^*(s)) = \sum_{1 \leq k \leq m^*} \beta_k(s) e_k^* \)) does not require the explicit computation of the mapping \( \Phi^*(s) \) since Eq.2 can be written only in terms of the kernel.

Working in a centered feature space, some important (often mistakenly ignored) comments follow. We show that the fundamental property of the mapped input points \( \| \Phi^*(s_i) \|^2 = w(s_i, s_i) = 1 \) can be greatly improved in a centered feature space. To do so, we define the mean in feature space \( \bar{\Phi}^*(\in \mathbb{R}^{p-1}) = \frac{1}{p} \sqrt{\Lambda^*} \Psi^* T H W \mathbf{1}_p \) and consider some properties of the feature points mapped under:

\[
\hat{\Phi}^*: \chi \rightarrow \mathbb{R}^{p-1}, \quad s \mapsto \hat{\Phi}^* + \Phi^*(s). \tag{4}
\]

Under this mapping, the training samples verify: \( \langle \hat{\Phi}^*(s_i), \hat{\Phi}^*(s_j) \rangle = w(s_i, s_j) - \hat{\Phi}^* s_i^2 \), with \( 0 \leq \hat{\Phi}^* \leq 1 \). The adjacency matrix \( W \) therefore gives (up to an additional factor \( \hat{\Phi}^* s_i^2 \)) the inner product between two points in the feature space under the mapping \( \hat{\Phi}^* \). The constant \( \hat{\Phi}^* \) has a simple geometric interpretation. In the feature space, the \( p \) non-centered training points, which belong to the unit sphere, define an affine space that is isomorphic to \( \mathbb{R}^{p-1} \). This affine space, spanned by the vectors \( \{ e_1^*, \ldots, e_{p-1}^* \} \), is at distance \( \hat{\Phi}^* \) from the origin \( \mathbf{0} \). Consequently, feature points mapped under \( \hat{\Phi}^*: s \mapsto \hat{\Phi}^* + \Phi^*(s) \) all belong to an hypersphere of \( \mathbb{R}^{p-1} \) of radius \( r_p = \sqrt{1 - \hat{\Phi}^* s_i^2} \).
i.e. \( S_{p-1}(0, r_p) \). This implies that, for all training sample \( s_i \in \Gamma \), we have \( \| \tilde{\Phi}^*(s_i) \| = r_p \). This normalization property of training samples is stronger than the usual property \( \| \tilde{\Phi}^*(s_i) \| = 1 \) and will prove important in the next section\(^1\).

In particular, this allows us to rephrase some pre-image methods, such as\[6\], in a centered feature space, leading to better results (sect 4). Finally, we note that the mapping \( \tilde{\Phi}^* \) can be deduced from \( \Phi^* \) by \( \Phi^* : \chi \rightarrow \mathbb{R}^p, s \mapsto (\tilde{\Phi}^*(s))^T \).

### 3. PRE-IMAGE

Given a point in the feature space \( \psi \), the pre-image problem consists in finding a point \( s \in \chi \) in the input space such that \( \Phi(s) = \psi \), i.e. the pre-image of \( \psi \). The exact pre-image might not exist (when it exists, it might also not be unique) and the pre-image problem is ill-posed \[6, 3, 5, 4\]. To circumvent this problem, one usually settles for an approximate solution and search for a pre-image that optimizes a given optimality criterion in the feature space. The pre-image problem has received a lot of attention in kernel methods \[6, 3, 5, 4\] and different optimality criteria have been proposed. Although most of those are based on the property \( \| \tilde{\Phi}^*(s_i) \|^2 = 1 \), significant improvement can be attained by considering that the mapped feature points \( \tilde{\Phi}^*(s_i) \) belong to the hypersphere \( S_{p-1}(0, r_p) \) (or equivalently stated that \( \| \tilde{\Phi}^*(s_i) \| = r_p \)). In particular, we insist on the fact that the popular normalization \( \frac{\Phi^*(s)}{\| \Phi^*(s) \|} \) is not equivalent to the normalization \( \frac{\tilde{\Phi}^*(s)}{\| \tilde{\Phi}^*(s) \|} \). In more detail, note that after normalization by the former criterion, a feature point does not belong any longer to the affine space defined by the \( p \)-training points. This behavior can also be seen in Figure 1b), which is the two dimensional visualization of the affine subspace (red circle) in Figure 1a). Figure 1a) shows the sphere \( S \) and the layout of feature points on \( S \).

The extended mapping of a new input point does not lie on the sphere (visualized as a purple point). As can be clearly seen the normalization as proposed in \[6\] projects the feature point (purple) onto the sphere (white). But the projected point does not lie in the span. This is clearly problematic as the principal modes of variations span only this affine space. The later normalization is the correct one and should be advantageously used. Therefore, we capitalize on our careful analysis of KPCA and define the different optimality criteria in centered feature space:

\[
\text{Distance: } s = \arg \min_{z \in \chi} \| \tilde{\Phi}^*(z) - \tilde{\psi}^* \|^2, \quad (5)
\]

\[
\text{Collinearity: } s = \arg \max_{z \in \chi} \left\langle \frac{\tilde{\Phi}^*(z)}{\| \tilde{\Phi}^*(z) \|}, \frac{\tilde{\psi}^*}{\| \tilde{\psi}^* \|} \right\rangle, \quad (6)
\]

where \( \tilde{\psi}^* = \tilde{\Phi}^* + \psi^* \). Recently, Arias and coworkers\[6\] have shown the connections between the out-of-sample and

\(^1\)Note that to compute the radius value \( r_p \) (or, equivalently, the distance \( \tilde{\Phi}^* \)), it is sufficient to compute \( \| \tilde{\Phi}^*(s_i) \| \) for only one of the training samples \( s_i \in \Gamma \).

---

**Fig. 2.** Digit images corrupted by additive Gaussian noise (from top to bottom, \( \sigma = 0.25, 0.45, 0.65 \)). The different rows respectively represent: the original digits and corrupted digits; different reconstruction methods: \[3\] ; \[3\] with normalization ; \[3\] ; \[5\] with normalization.

The pre-image problems and proposed a normalized optimality criterion addressing the important lack of normalization in kernel methods:

\[
s = \arg \min_{z \in \chi} \| \tilde{\Phi}^*(z) - \tilde{\psi}^* \|^2 \quad \text{with} \quad \tilde{\psi} = r_p \frac{\tilde{\psi}^*}{\| \tilde{\psi}^* \|}. \quad (7)
\]

Instead of solving directly for the pre-image in Eq.7, they first estimate the optimal kernel vector \( p^*_\psi \) as a standard least-squares problem \( p^*_\psi = \tilde{\Psi} \sqrt{\Lambda} (\tilde{\psi} - \tilde{\Phi}^*) \) and then use previous methods\[3, 5\] to estimate the optimal pre-image.

### 4. APPLICATION IN IMAGE DENOISING

In order to validate the proposed algorithm, we run experiments on real world data. We test our pre-image algorithm on
the denoising of noisy images and compare our approach to
previous methods. The computation of Kernel PCA is done
using the Gaussian kernel \( \exp\left(-d^2(s_i, s_j)/\sigma^2\right) \) where \( \sigma \) is
the median over all distances between points[6].

To test the performance of our approach on the task
of image denoising, we apply the algorithm on the USPS
dataset of handwritten digits\(^2\). We show that our normal-
ization method improves two recent state-of-the-art algo-
rithms [3], [5]. Therefore, we form two training sets com-
posed of randomly selected samples (60 and 200 respectively)
for each of the ten digits. The test set is composed of 60
images randomly selected and corrupted by some additive
Gaussian noise at different noise levels. The process of de-
noising simply amounts to estimating the pre-images of the
feature vectors given by the Nyström extension of the noisy
samples. In the case of Kernel PCA, we use the first \( m^* = 8 \)
eigenvectors \( \{e_1^*, \ldots, e_m^*\} \) to compute projections in feature
space.

Table 1. Average PSNR (in dB) of the denoised images cor-
rupted by different noise level. Training set is composed of 60
samples (first 4 rows) and 200 samples (last 4 rows). The first
and third column show the denoising results without and the
second and last columns with the normalization as proposed
in this paper.

Figure 2 displays some of the computed pre-images us-
ing different methods. Table 1 shows a quantitative compari-
on between different methods based on the pixel-signal-to-
noise ratio(PSNR). Our normalisation method improves visu-
ally and quantitatively both pre-image methods. The results
confirm that the new normalisation criterion in centered fea-
tures space (second and fourth column) yields better results
than previous pre-image methods (first and third column).

5. CONCLUSION

In this paper, we focused on the pre-image problem in ker-
nel methods such as Kernel PCA. We espacially focussed on
the issue of correctly normalizing in centered feature space.
A geometric interpretation eased the understanding of oper-
ations involved when working with centered data in feature
space. As a consequence, we deduced a new normalization
criterion for previous proposed pre-image methods. The the-
oretical results could be nicely verified at hand of computed
examples.
