Abstract

The present manuscript presents a framework for automating the formulation and resolution of limit analysis problems in a very general manner. This framework relies on FEniCS domain-specific language and the representation of material strength criteria and their corresponding support function in the conic programming setting. Various choices of finite element discretization, including discontinuous Galerkin interpolations, are offered by FEniCS, enabling to formulate lower bound equilibrium elements or upper bound elements including discontinuities for instance. The numerical resolution of the corresponding optimization problem is carried out by the interior-point solver Mosek which takes advantage of the conic representation for yield criteria. Through various illustrative examples ranging from classical continuum limit analysis problems to generalized mechanical models such as plates, shells, strain gradient or Cosserat continua, we show that limit analysis problems can be formulated using only a few lines of code, discretized in a very simple manner and solved extremely efficiently. This paper is accompanied by a FEniCS toolbox implementing the above-mentioned framework.

Keywords: limit analysis, yield design, convex optimization, conic programming, FEniCS, generalized continua

1. Introduction

Limit analysis [27], or more generally yield design theory [59, 60], is an efficient method for computing the ultimate load, or bearing capacity, of a structure based on the sole knowledge of a given local strength criterion (or plasticity criterion for limit analysis) and applied external loads. Its main advantage is that it is a direct method i.e. it solves directly for the limit load instead of relying on incremental elasto-plastic analysis and requires only few mechanical information to solve the limit load problem. More precisely, limit analysis theory can be formulated as a convex optimization problem and therefore benefits from variational approximations on the primal and associated dual problem yielding the so-called lower bound static and upper bound kinematic approaches. The exact collapse load can therefore be bracketed by the bounding status of the static and kinematic solutions. This method has found tremendous applications in mechanical and civil engineering problems since analytical upper bounds can be obtained very efficiently by considering simple collapse mechanisms but also because lower bounds provide a safe approximation to the exact collapse load. Typical fields of application include soil slope stability, footing bearing capacity or other geotechnical problems [17], rigid-block masonry structures, design of reinforced-concrete structures [16, 55], especially through strut-and-tie methods [63] or yield-line analysis [31], collapse loads of frame, plate or shell structures [61, 62], etc.

In all the above-mentioned applications, hand-based solutions are quite easy to compute and can be found in different design codes. However, limit analysis techniques have been somehow limited to hand-based solutions for quite a long time because of the difficulties encountered in the past when automating their resolution in a finite-element discrete setting for instance. Indeed, the corresponding optimization problems are inherently non-smooth and large-scale which makes them challenging to solve. Standard gradient-based optimizers for instance are not a good candidate for their resolution due to the highly non-smooth aspect. The major breakthrough in this field is associated with the development of efficient optimization algorithms particularly well-suited for this class of optimization problems. The first progress has been made with the simplex algorithm [19] for solving linear programming (LP) problems. However, limit analysis problems fall into the LP category only when the strength criterion is a polytope i.e. when it can be written as a

34 collection of linear inequalities [1, 64], whereas the majority of strength/plasticity criteria are non-linear. The
 35 second progress has been achieved with the advent of so-called *interior-point* (IP) solvers which improved
 36 the complexity of solving LP problems [33], the simplex algorithm has exponential complexity compared
 37 to polynomial (and, in practice, quasi-linear) complexity for interior-point solvers. More importantly, the
 38 interior-point method has been extended to more complex convex programs [53] such as second-order cone
 39 programs (SOCP) or semi-definite programs (SDP). Combining the weak complexity of IP solvers and the
 40 fact that most strength criteria can be expressed using second-order cone or semi-definite constraints [3, 45]
 41 now enables to solve complex and large-scale limit analysis problems [40, 48, 57, 67]. Obviously, a few other
 42 alternative methods have been proposed but, to the authors' opinion, none of them have been shown to
 43 exhibit a performance similar to state-of-the-art IP solvers.

44 As regards numerical discretization techniques for limit analysis problem, the vast majority of works relies
 45 on the finite-element method [44, 1, 56]. The specificity of limit analysis problems, compared to more standard
 46 nonlinear computations with displacement-based FE discretizations, lies in the use of static equilibrium-based
 47 finite-elements for obtaining true lower bound [64, 34] (and therefore safe) estimates of the limit load but also
 48 in the use of discontinuous finite-elements for the kinematic upper bound approach [65, 47, 46]. Indeed, most
 49 hand-based upper bound solutions have been obtained considering rigid-block mechanisms, thus involving
 50 no deformation but only displacement jumps in the plastic dissipation computation. Despite the higher
 51 computational cost compared to equivalent continuous interpolations, discontinuous interpolations provide
 52 more accurate limit load estimates [56, 65, 39, 47], especially if finite-element edges are well-oriented. They
 53 are also more robust for certain problems since they do not suffer from locking issues, see for instance [51]
 54 for volumetric locking in pressure-insensitive materials or [9] for shear-locking in thin plates.

55 Due to the specific nature of the optimization problems, formulating a discretized version of a limit
 56 analysis (either static or kinematic) approach requires forming matrices representing, for instance, equilib-
 57 rium, continuity or boundary conditions but also other linear relations coupling mechanical variables (such
 58 as stress or strain) with auxiliary variables used to express the strength conditions in a LP/SOCP or SDP
 59 format. Besides, depending on the specific choice made for the optimization solver, the standard input
 60 format of the problem may differ. As a result, discrete limit analysis problems require access to matrices that
 61 are not readily available from standard displacement-based FE solver and must therefore be implemented
 62 in an external program before calling the optimizer. Combining this aspect with the various types of FE
 63 discretizations and mechanical models makes the automation of limit analysis problem a challenge. As
 64 a result, limit analysis codes are usually limited to specific situations, sometimes with specific strength criteria.

65
 66 In the present manuscript, we describe a general framework for the formulation of limit analysis problems
 67 for different mechanical models (2D/3D continua, plates/shells or generalized continua). Relying on the
 68 FEniCS finite-element library and symbolic representation of operators and code-generation capabilities,
 69 different FE discretization schemes (including discontinuous or equilibrium elements) can be easily formulated
 70 and generalized to more advanced mechanical models. The proposed framework therefore offers four levels
 71 of generality in the problem formulation:

- 72 • choice of a *mechanical model*: limit analysis problems possess the same structure and can be formulated
 73 in a symbolic fashion through generalized stress/strain definitions (section 2).
- 74 • choice of a *strength criterion*: the formulation of its conic representation at a local point suffices to
 75 completely characterize the strength criterion, its translation to the global optimization problem being
 76 automatically performed (section 3).
- 77 • choice of a *FE discretization*: including element type, interpolation degree or quadrature rule, all
 78 compatible for a variable number of degrees of freedom related to the choice of the mechanical model
 79 (section 4).
- 80 • choice of the *optimization solver*: although the accompanying FEniCS toolbox relies extensively on the
 81 *Mosek* optimization solver [49], once formulated in a standard conic programming form, the problem
 82 can then be written in a specific file format appropriate for another solver.

83 This versatility is further illustrated by considering homogenization theory in a limit analysis setting (section
 84 5), plate and shell problems (section 6) and generalized continua such as Cosserat or strain gradient models
 85 (section 7).

86 As regards numerical implementation, the present paper is accompanied by a Python module
 87 `fenics_optim.limit_analysis` implemented as a submodule of the FEniCS convex optimization package
 88 `fenics_optim` [6] described in [5].

89 *Notations.* $\mathbf{A} : \mathbf{B} = A_{ij}B_{ji}$, $\mathcal{A} : \mathcal{B} = \mathcal{A}_{ijk}\mathcal{B}_{kji}$.

90 2. A general framework for limit analysis problems

91 In this section, we consider a material domain $\Omega \subset \mathbb{R}^d$ (with $d = 1, 2, 3$) associated with a specific
 92 mechanical model. In the subsequent applications, we will consider classical continuum theories such as 2D
 93 or 3D Cauchy continua or Reissner-Mindlin plate models for instance but also generalized continuum models
 94 encompassing higher-grade or higher-order theories. For this reason, the subsequent presentation will be
 95 made in a generalized continuum framework in which the mechanical stress or strain measures, equilibrium
 96 or continuity equations and boundary conditions will be written in an abstract fashion, their precise expression
 97 remaining to be specified for each particular mechanical theory. In particular, the presentation will be in the
 98 line of Germain's construction through the virtual work principle [24, 23].

99 2.1. Virtual work principle for generalized continua

100 Let us therefore consider a generalized virtual velocity field $\mathbf{u}(\mathbf{x})$ of dimension n and a set of strain
 101 measures $\mathbf{D}\mathbf{u}$ of dimension m with \mathbf{D} being a generalized strain operator. Following [24, 23], such strain
 102 measures must be objective i.e. null for any rigid body motion. The virtual power of internal forces is
 103 assumed to be given by an internal force density depending linearly upon the strain measures:

$$\mathcal{P}^{(i)}(\mathbf{u}) = - \int_{\Omega} \boldsymbol{\Sigma} \cdot \mathbf{D}\mathbf{u} \, dx \quad (1)$$

104 in which $\boldsymbol{\Sigma}$ denotes the generalized stress measure associated with $\mathbf{D}\mathbf{u}$ by duality. The above expression
 105 must in fact be understood in the sense of distributions i.e. \mathbf{u} may exhibit discontinuities $\mathbf{J}\mathbf{u}$ (consistent
 106 with the definition of operator \mathbf{D}) across some internal surface Γ . The power of internal forces therefore
 107 writes more explicitly as:

$$\mathcal{P}^{(i)}(\mathbf{u}) = - \left(\int_{\Omega \setminus \Gamma} \boldsymbol{\Sigma} \cdot \mathbf{D}\mathbf{u} \, dx + \int_{\Gamma} \boldsymbol{\Sigma} \cdot \mathbf{J}\mathbf{u} \, dS \right) \quad (2)$$

108 The power of external forces is assumed to consist of two contributions: long-range interaction forces described
 109 by a volume density \mathbf{F} and boundary contact forces described by a surface density \mathbf{T} acting on the exterior
 110 boundary $\partial\Omega$. Each power density depends linearly upon the generalized velocity so that the total power is
 111 given by:

$$\mathcal{P}^{(e)}(\mathbf{u}) = \int_{\Omega} \mathbf{F} \cdot \mathbf{u} \, dx + \int_{\partial\Omega} \mathbf{T} \cdot \mathbf{u} \, dS \quad (3)$$

112 According to the virtual power principle, the system is in equilibrium if and only if the sum of the internal
 113 and external virtual powers is zero for any virtual velocity field:

$$\mathcal{P}^{(i)}(\mathbf{u}) + \mathcal{P}^{(e)}(\mathbf{u}) = 0 \quad \forall \mathbf{u} \quad (\text{equilibrium})$$

114 2.2. General formulation of a limit analysis problem

115 Limit analysis (or yield design) theory amounts to finding the maximum loading a system can sustain
 116 considering only equilibrium and strength conditions for its constitutive material. The latter can be generally
 117 described by the fact that the generalized stresses $\boldsymbol{\Sigma}(\mathbf{x})$ must belong to a strength domain $G(\mathbf{x})$ for all point
 118 $\mathbf{x} \in \Omega$:

$$\boldsymbol{\Sigma}(\mathbf{x}) \in G(\mathbf{x}) \quad \forall \mathbf{x} \in \Omega \quad (\text{strength condition})$$

119 The strength domain $G \subseteq \mathbb{R}^m$ is assumed to be a convex set (it may be unbounded and non-smooth) which
 120 usually contains the origin $0 \in G$.

121

Finding the maximum loading will be achieved with respect to a given loading *direction* i.e. by assuming that both volume and surface forces depend upon a single load factor λ in an affine manner:

$$\mathbf{F}(\lambda) = \lambda \mathbf{f} + \mathbf{f}_0 \quad (4)$$

$$\mathbf{T}(\lambda) = \lambda \mathbf{t} + \mathbf{t}_0 \quad (5)$$

where \mathbf{f}, \mathbf{t} are given loading directions and $\mathbf{f}_0, \mathbf{t}_0$ are fixed reference loads. In such a case, the power of external forces can also be written in an affine manner with respect to λ :

$$\mathcal{P}_\lambda^{(e)}(\mathbf{u}) = \lambda \mathcal{P}^{(e)}(\mathbf{u}) + \mathcal{P}_0^{(e)}(\mathbf{u}) \quad (6)$$

with obvious notations. Let us mention that if one wants to describe the set of ultimate loads defined by multiple loading parameters (see for instance section 5), the ultimate load factor λ^+ must be computed independently for each fixed loading direction in the multiple loading parameter space. When repeating this process for different loading directions, one obtains the corresponding set of ultimate loads.

The limit analysis problem can finally be formulated as finding the maximum load factor λ such that there exists a generalized stress field $\Sigma(\mathbf{x})$ in equilibrium with $(\mathbf{F}(\lambda), \mathbf{T}(\lambda))$ and complying with the material strength properties i.e. satisfying both (**equilibrium**) and (**strength condition**) which can also be written as:

$$\begin{aligned} \lambda^+ = \sup_{\lambda, \Sigma} \quad & \lambda \\ \text{s.t.} \quad & \mathcal{P}^{(i)}(\mathbf{u}) + \lambda \mathcal{P}^{(e)}(\mathbf{u}) + \mathcal{P}_0^{(e)}(\mathbf{u}) = 0 \quad \forall \mathbf{u} \\ & \Sigma(\mathbf{x}) \in G(\mathbf{x}) \quad \forall \mathbf{x} \in \Omega \end{aligned} \quad (7)$$

Let us mention that for the infinite-dimensional convex problem (7) to have a solution, the fixed loading $(\mathbf{f}_0, \mathbf{t}_0)$ must be a sustainable loading i.e. there must exist a stress field in equilibrium with $(\mathbf{f}_0, \mathbf{t}_0)$ and satisfying (**strength condition**).

Formulation (7) will be the basis of the mixed finite-element formulation discussed in section 4.3 when choosing proper interpolation spaces for Σ and \mathbf{u} . We now turn to the general formulation of the static and kinematic approaches.

2.2.1. Static approach

Starting from the weak formulation of equilibrium given by (**equilibrium**), strong balance equations, continuity conditions and boundary conditions can be obtained for the generalized stresses Σ . These will generally take the following form:

$$\mathcal{E}\Sigma + \lambda \mathbf{f} + \mathbf{f}_0 = 0 \quad \text{in } \Omega \quad (8)$$

$$\mathcal{C}\Sigma = 0 \quad \text{on } \Gamma \quad (9)$$

$$\mathcal{T}\Sigma = \lambda \mathbf{t} + \mathbf{t}_0 \quad \text{on } \partial\Omega \quad (10)$$

where \mathcal{E} is an equilibrium operator (adjoint to \mathcal{D}) and \mathcal{C} and \mathcal{T} are some continuity and trace operators related to \mathcal{E} . A generalized stress field $\Sigma(\mathbf{x})$ satisfying these conditions will be termed as *statically admissible* with a given loading $(\lambda \mathbf{f} + \mathbf{f}_0, \lambda \mathbf{t} + \mathbf{t}_0)$.

The pure static formulation can therefore be generally written as:

$$\begin{aligned} \lambda^+ = \sup_{\lambda, \Sigma} \quad & \lambda \\ \text{s.t.} \quad & \mathcal{E}\Sigma + \lambda \mathbf{f} + \mathbf{f}_0 = 0 \quad \text{in } \Omega \\ & \mathcal{C}\Sigma = 0 \quad \text{on } \Gamma \\ & \mathcal{T}\Sigma = \lambda \mathbf{t} + \mathbf{t}_0 \quad \text{on } \partial\Omega \\ & \Sigma(\mathbf{x}) \in G(\mathbf{x}) \quad \forall \mathbf{x} \in \Omega \end{aligned} \quad (\text{SA})$$

Obviously Σ must belong to an appropriate functional space \mathcal{W} consistent with the nature of the above operators. If one restricts to a (finite-dimensional) subset $\mathcal{W}_h \subset \mathcal{W}$ such that all constraints of (SA) can be satisfied exactly, the corresponding solution λ_s of the corresponding (finite) convex optimization problem will therefore be a lower bound to the exact limit load: $\lambda_s \leq \lambda^+$.

148 *2.2.2. Kinematic approach*

149 The kinematic formulation of a limit analysis problem can be obtained from an equivalent formulation of
 150 (7):

$$\lambda \leq \lambda^+ \iff \exists \boldsymbol{\Sigma} \text{ s.t. } \begin{cases} \lambda \mathcal{P}^{(e)}(\mathbf{u}) + \mathcal{P}_0^{(e)}(\mathbf{u}) = -\mathcal{P}^{(i)}(\mathbf{u}) & \forall \mathbf{u} \\ \boldsymbol{\Sigma}(\mathbf{x}) \in G(\mathbf{x}) & \forall \mathbf{x} \in \Omega \end{cases} \quad (11)$$

151 One therefore has that:

$$\lambda \mathcal{P}^{(e)}(\mathbf{u}) + \mathcal{P}_0^{(e)}(\mathbf{u}) \leq \sup_{\boldsymbol{\Sigma}(\mathbf{x}) \in G(\mathbf{x})} \{-\mathcal{P}^{(i)}(\mathbf{u})\} = \mathcal{P}^{(mr)}(\mathbf{u}) \quad \forall \mathbf{u} \quad (12)$$

152 where we introduced the maximum resisting power as:

$$\mathcal{P}^{(mr)}(\mathbf{u}) = \int_{\Omega \setminus \Gamma} \pi_G(\mathbf{D}\mathbf{u}) \, dx + \int_{\Gamma} \pi_G(\mathbf{J}\mathbf{u}) \, dS \quad (13)$$

153 in which π_G is the support function of the convex set G :

$$\pi_G(\mathbf{d}) = \sup_{\boldsymbol{\Sigma} \in G} \{\boldsymbol{\Sigma} \cdot \mathbf{d}\} \quad (14)$$

154 One can conclude that:

$$\lambda \leq \lambda^+ \implies \lambda \leq \frac{\mathcal{P}^{(mr)}(\mathbf{u}) - \mathcal{P}_0^{(e)}(\mathbf{u})}{\mathcal{P}^{(e)}(\mathbf{u})} \quad \forall \mathbf{u} \quad (15)$$

155 Minimizing the right-hand side of the above relation therefore gives an upper bound to the exact maximal
 156 load λ^+ . Under appropriate mathematical assumptions [52, 22] (non-restrictive in practice), it can be shown
 157 that the minimum is in fact λ^+ so that one has:

$$\lambda^+ = \inf_{\mathbf{u}} \frac{\mathcal{P}^{(mr)}(\mathbf{u}) - \mathcal{P}_0^{(e)}(\mathbf{u})}{\mathcal{P}^{(e)}(\mathbf{u})} \quad (16)$$

158 Observing that the above quotient is invariant when rescaling \mathbf{u} by a positive factor, a normalization con-
 159 straint can in fact be considered to remove the denominator so that, one finally has for the kinematic
 160 approach:

$$\begin{aligned} \lambda^+ &= \inf_{\mathbf{u}} \mathcal{P}^{(mr)}(\mathbf{u}) - \mathcal{P}_0^{(e)}(\mathbf{u}) \\ &\text{s.t. } \mathcal{P}^{(e)}(\mathbf{u}) = 1 \end{aligned} \quad (\text{KA})$$

161 Similarly to the static approach (SA), \mathbf{u} must belong to an appropriate functional space \mathcal{V} . If one restricts
 162 to a (finite-dimensional) subset $\mathcal{V}_h \subset \mathcal{V}$, the corresponding solution λ_u of the corresponding (finite) convex
 163 optimization problem will therefore be an upper bound to the exact limit load: $\lambda^+ \geq \lambda_u$.

164 **3. Conic representation of strength criteria**

165 This section deals with the representation of material strength criteria or associated support functions in
 166 the framework of conic programming. The first subsection describes the standard conic programming format
 167 used by the Mosek solver although other solvers (e.g. CVXOPT, Sedumi, SDPT3) use a format which is
 168 quite similar. We then discuss how the conic programming framework is used for limit analysis problems.

169 *3.1. Conic programming*

170 Optimization problems entering the *conic programming framework* can be written as:

$$\begin{aligned} \min_{\mathbf{x}} \quad & \mathbf{c}^T \mathbf{x} \\ \text{s.t.} \quad & \mathbf{b}_l \leq \mathbf{A}\mathbf{x} \leq \mathbf{b}_u \\ & \mathbf{x} \in \mathcal{K} \end{aligned} \quad (17)$$

171 where vector \mathbf{c} defines a linear objective functional, matrix \mathbf{A} and vectors $\mathbf{b}_u, \mathbf{b}_l$ define linear inequality (or
 172 equality if $\mathbf{b}_u = \mathbf{b}_l$) constraints and where $\mathcal{K} = \mathcal{K}^1 \times \mathcal{K}^2 \times \dots \times \mathcal{K}^p$ is a product of cones $\mathcal{K}^i \subset \mathbb{R}^{d_i}$ so that
 173 $\mathbf{x} \in \mathcal{K} \iff \mathbf{x}^i \in \mathcal{K}^i \forall i = 1, \dots, p$ where $\mathbf{x} = (\mathbf{x}^1, \mathbf{x}^2, \dots, \mathbf{x}^p)$. These cones can be of different kinds:

- 174 • $\mathcal{K}^i = \mathbb{R}^{d_i}$ i.e. no constraint on \mathbf{x}^i
- 175 • $\mathcal{K}^i = (\mathbb{R}^+)^{d_i}$ is the positive orthant i.e. $\mathbf{x}^i \geq 0$
- 176 • $\mathcal{K}^i = \mathcal{Q}_{d_i}$ the quadratic Lorentz cone defined as:

$$\mathcal{Q}_{d_i} = \{\mathbf{z} \in \mathbb{R}^{d_i} \text{ s.t. } \mathbf{z} = (z_0, \bar{\mathbf{z}}) \text{ and } z_0 \geq \|\bar{\mathbf{z}}\|_2\} \quad (18)$$

- 177 • $\mathcal{K}^i = \mathcal{Q}_{d_i}^r$ the rotated quadratic Lorentz cone defined as:

$$\mathcal{Q}_{d_i}^r = \{\mathbf{z} \in \mathbb{R}^{d_i} \text{ s.t. } \mathbf{z} = (z_0, z_1, \bar{\mathbf{z}}) \text{ and } 2z_0z_1 \geq \|\bar{\mathbf{z}}\|_2^2, z_0, z_1 \geq 0\} \quad (19)$$

- 178 • $\mathcal{K}^i = \mathbb{S}_{n_i}^+$ is the cone of semi-definite positive matrices of dimension n_i .
- 179 • $\mathcal{K}^i = \mathcal{P}_{d_i}^\alpha$ is the (primal) power cone parametrized by α s.t. $0 < \alpha < 1$:

$$\mathcal{P}_{d_i}^\alpha = \{\mathbf{z} \in \mathbb{R}^{d_i} \text{ s.t. } \mathbf{z} = (z_0, z_1, \bar{\mathbf{z}}) \text{ and } z_0^\alpha z_1^{1-\alpha} \geq \|\bar{\mathbf{z}}\|_2, z_0, z_1 \geq 0\} \quad (20)$$

- 180 • $\mathcal{K}^i = \mathcal{K}_{\text{exp}}$ is the (primal) exponential cone:

$$\mathcal{K}_{\text{exp}} = \{\mathbf{z} \in \mathbb{R}^3 \text{ s.t. } \mathbf{z} = (z_0, z_1, z_2) \text{ and } z_0 \geq z_1 \exp(z_2/z_1), z_0, z_1 \geq 0\} \quad (21)$$

181

182 If \mathcal{K} contains only cones of the first two kinds, then the resulting optimization problem (17) belongs to
 183 the class of Linear Programming (LP) problems. If, in addition, \mathcal{K} contains quadratic cones \mathcal{Q}_{d_i} or $\mathcal{Q}_{d_i}^r$, then
 184 the problem belongs to the class of Second-Order Cone Programming (SOCP) problems. When cones of the
 185 type $\mathbb{S}_{n_i}^+$ are present, the problem belongs to the class of Semi-Definite Programming (SDP) problems. LP,
 186 SOCP and SDP are extremely important classes of convex optimization problems for which a tremendous
 187 number of applications can be found. When a conic optimization problem contains a power (resp. exponential
 188 cone), one obtains a power (resp. exponential) cone programming problem. Such problems have not been
 189 investigated much until recently due to the difficulty of developing efficient solvers. Only a few solvers now
 190 provide efficient algorithms for solving power and exponential cone programs, including ECOS [21] and Mosek
 191 (since version 9).

192 3.2. Conic-representable functions and sets

193 In order to use conic programming solvers for our application, limit analysis problems must therefore be
 194 formulated following format (17). Inspecting the structure of (SA), it can be seen that all constraints and
 195 the objective functions are linear, except for the strength condition (**strength condition**). As a result, in
 196 order to fit format (17), only (**strength condition**) must be reformulated in a conic sense. Similarly for
 197 problem (KA), only the support function π_G must be expressed in conic form to fit the standard format (17).
 198 This reformulation step therefore depends on the specific choice of a strength criterion. To do so, we define
 199 a generic form of *conic-representable* functions and sets. The `fenics_optim` package [6] relies on this specific
 200 notion for automating the formulation of generic convex problems. The `fenics_optim.limit_analysis`
 201 module accompanying this paper uses these notions and particularizes them for limit analysis problems.

202 Conic-representable functions are defined as the class of convex functions which can be expressed as
 203 follows:

$$F(\mathbf{x}) = \min_{\mathbf{y}} \mathbf{c}_x^T \mathbf{x} + \mathbf{c}_y^T \mathbf{y} \quad (22)$$

$$\text{s.t. } \mathbf{b}_l \leq \mathbf{A}\mathbf{x} + \mathbf{B}\mathbf{y} \leq \mathbf{b}_u$$

$$\mathbf{y} \in \mathcal{K}$$

204 with $\mathbf{x} \in \mathbb{R}^n$ and in which \mathcal{K} is again a product of cones of the kinds detailed in section 3.1. As a by-
 205 product of the previous definition, *conic-representable convex sets* correspond to sets for which the indicator
 206 function is conic-representable. If \mathcal{K} contains only second-order cones (SOC), then we will speak about a
 207 *SOC-representable* function. A *SDP-representable* function corresponds to the case when \mathcal{K} contains SDP
 208 cones, whereas *linear-representable* functions correspond to the case when the conic constraint $\mathbf{y} \in \mathcal{K}$ is
 209 absent or contains only positive constraints $y_i \geq 0$.

210 It is easy to see that if F is SOC-representable (resp. SDP-representable, resp. linear-representable),
 211 then its Legendre-Fenchel conjugate F^* is also SOC-representable (resp. SDP-representable, resp. linear-
 212 representable). For limit analysis applications, this means that if a strength criterion (expressed as a convex
 213 set) is SOC-representable (resp. SDP-representable, resp. linear-representable), then so will be its support
 214 function, and vice-versa.

215 As already mentioned in [3, 37, 45], a large class of classical strength criteria can be formulated in terms
 216 of second-order cone (SOC) constraints or semi-definite positive (SDP) matrix constraints so that their
 217 expression or their support function expressions can be expressed in the form (22). For some more advanced
 218 strength criteria, their conic representation may involve power or exponential cones. This is the case, for
 219 instance, for the Generalized Hoek-Brown [41] or the Hosford yield criterion which are both power-cone
 220 representable. Below, we give an example on how conic-representation is used for the case of a 2D plane-
 221 strain Mohr-Coulomb criterion and for the plane-stress Hosford criterion. Many generic conic reformulations
 222 can be found in [42, 2, 12] and especially in the Mosek Modeling Cookbook [50].

223 3.3. Example of the plane-strain Mohr-Coulomb criterion

224 In plane-strain conditions, the Mohr-Coulomb criterion with cohesion c and friction angle ϕ writes as:

$$\boldsymbol{\sigma} \in \text{MC}_{2D}(c, \phi) \iff \sqrt{(\sigma_{xx} - \sigma_{yy})^2 + 4\sigma_{xy}^2} \leq 2c \cos \phi - (\sigma_{xx} + \sigma_{yy}) \sin \phi \quad (23)$$

which can be also written as:

$$\sqrt{y_1^2 + y_2^2} \leq y_0 \iff \mathbf{y} \in \mathcal{Q}_3 \quad (24)$$

$$\text{with } \begin{Bmatrix} y_0 \\ y_1 \\ y_2 \end{Bmatrix} = \begin{bmatrix} -\sin \phi & -\sin \phi & 0 \\ 1 & -1 & 0 \\ 0 & 0 & 2 \end{bmatrix} \begin{Bmatrix} \sigma_{xx} \\ \sigma_{yy} \\ \sigma_{xy} \end{Bmatrix} + \begin{Bmatrix} 2c \cos \phi \\ 0 \\ 0 \end{Bmatrix} \quad (25)$$

225 This expression shows that the criterion is SOC-representable in the sense of format (22).
 226

Similarly, its support function is given by:

$$\begin{aligned} \pi(\mathbf{d}) &= \sup_{\boldsymbol{\sigma} \in \text{MC}_{2D}(c, \phi)} \sigma_{ij} d_{ij} \quad (26) \\ &= \begin{cases} c \cotan \phi \operatorname{tr}(\mathbf{d}) & \text{if } \operatorname{tr}(\mathbf{d}) \geq \sin \phi \sqrt{(d_{xx} - d_{yy})^2 + 4d_{xy}^2} \\ +\infty & \text{otherwise} \end{cases} \end{aligned}$$

which can be expressed as:

$$\begin{aligned} \pi(\mathbf{d}) &= \min_{\mathbf{y}} c \cotan \phi \operatorname{tr}(\mathbf{d}) \quad (27) \\ \text{s.t. } &\begin{bmatrix} 1 & 1 & 0 \\ \sin \phi & -\sin \phi & 0 \\ 0 & 0 & 2 \sin \phi \end{bmatrix} \begin{Bmatrix} d_{xx} \\ d_{yy} \\ d_{xy} \end{Bmatrix} = \mathbf{y} \\ &\mathbf{y} \in \mathcal{Q}_3 \end{aligned}$$

which also fits format (22). Note that the representation is by no means unique since, for instance, we could have equivalently replaced the linear objective term by $c \cotan \phi y_0$ or we could also have inverted the linear relation between \mathbf{d} and \mathbf{y} and introduced $\tilde{\mathbf{y}} = \mathbf{y} / \sin \phi$ so that:

$$\begin{aligned} \pi(\mathbf{d}) &= \min_{\tilde{\mathbf{y}}} c \cos \phi \tilde{y}_0 \quad (28) \\ \text{s.t. } &\begin{Bmatrix} d_{xx} \\ d_{yy} \\ d_{xy} \end{Bmatrix} = \begin{bmatrix} (\sin \phi)/2 & 1/2 & 0 \\ (\sin \phi)/2 & -1/2 & 0 \\ 0 & 0 & 1/2 \end{bmatrix} \tilde{\mathbf{y}} \\ &\tilde{\mathbf{y}} \in \mathcal{Q}_3 \end{aligned}$$

227 This expression has the advantage over (27) of being still well-defined when $\phi = 0$, enabling to recover the
 228 Tresca/von Mises case.

229 *3.4. Example of the plane-stress Hosford criterion*

230 The isotropic Hosford yield criterion [28] can be seen as a generalization of the von Mises or Tresca criteria
 231 which writes in plane-stress conditions as follows:

$$\boldsymbol{\sigma} \in G_{\text{Hosford}} \iff \frac{1}{2} (|\sigma_I|^n + |\sigma_{II}|^n + |\sigma_I - \sigma_{II}|^n) \leq \sigma_0^n \quad (29)$$

232 where $\sigma_I \geq \sigma_{II}$ are the principal stresses, σ_0 the uniaxial strength and $n \geq 1$ a material parameter. In
 233 particular, one retrieves the plane-stress von Mises criterion for $n = 2$ and the Tresca criterion for $n = 1$ and
 234 $n \rightarrow \infty$. This criterion is often used to model metallic materials, Hosford suggesting to use $n = 8$ for fcc
 235 metals (e.g. aluminum) and $n = 6$ for bcc metals (e.g. ferritic steel) [29].

236 Apart from the special cases $n \in \{1, 2, \infty\}$, the previous criterion cannot be represented using simple
 237 second-order cone constraints for any n . We now show that it can be modeled efficiently using power cones.
 238 Let us first write:

$$\boldsymbol{\sigma} \in G_{\text{Hosford}} \iff \begin{cases} z_1 + z_2 + z_3 \leq 2\sigma_0^n \\ |\sigma_I| \leq (z_1)^{1/n} \\ |\sigma_{II}| \leq (z_2)^{1/n} \\ |\sigma_I - \sigma_{II}| \leq (z_3)^{1/n} \\ z_i \geq 0 \end{cases} \iff \begin{cases} z_1 + z_2 + z_3 \leq 2\sigma_0^n \\ |\bar{z}_i| \leq (z_i)^{1/n} \quad i = 1, 2, 3 \\ \sigma_I \leq \bar{z}_1 \\ -\sigma_{II} \leq \bar{z}_2 \\ \sigma_I - \sigma_{II} \leq \bar{z}_3 \\ z_i \geq 0 \end{cases} \quad (30)$$

where we introduced auxiliary variables z_i, \bar{z}_i . Let us now remark that the constraints $|\bar{z}_i| \leq (z_i)^{1/n}$ with
 $z_i \geq 0$ can be expressed using the three-dimensional power-cone constraint $(z_i, 1, \bar{z}_i) \in \mathcal{P}_3^{1/n}$. Besides, the
 principal stresses in 2D can be expressed as follows:

$$\sigma_I = \frac{\sigma_{xx} + \sigma_{yy}}{2} + \frac{1}{2} \sqrt{(\sigma_{xx} - \sigma_{yy})^2 + 4\sigma_{xy}^2} \quad (31)$$

$$\sigma_{II} = \frac{\sigma_{xx} + \sigma_{yy}}{2} - \frac{1}{2} \sqrt{(\sigma_{xx} - \sigma_{yy})^2 + 4\sigma_{xy}^2} \quad (32)$$

239 Introducing $\|\bar{\mathbf{y}}\|_2 = \sqrt{(\sigma_{xx} - \sigma_{yy})^2 + 4\sigma_{xy}^2}$ with $\bar{\mathbf{y}} = \begin{Bmatrix} \sigma_{xx} - \sigma_{yy} \\ 2\sigma_{xy} \end{Bmatrix}$, (30) can be rewritten as:

$$\boldsymbol{\sigma} \in G_{\text{Hosford}} \iff \begin{cases} z_1 + z_2 + z_3 \leq 2\sigma_0^n \\ (z_i, 1, \bar{z}_i) \in \mathcal{P}_3^{1/n} \quad i = 1, 2, 3 \\ \|\bar{\mathbf{y}}\|_2 \leq y_0 \\ (\sigma_{xx} + \sigma_{yy} + y_0)/2 = \bar{z}_1 \\ (-\sigma_{xx} - \sigma_{yy} + y_0)/2 = \bar{z}_2 \\ y_0 = \bar{z}_3 \end{cases} \quad (33)$$

240 where one can see that the Hosford criterion can be formulated using 3 power-cone constraints, 1 second-order
 241 cone constraint, 1 linear inequality and 3 equality constraints.

242

243 Finally, note that anisotropic versions (e.g. the Logan-Hosford yield criterion [43]) of the form:

$$A|\sigma_I|^n + B|\sigma_{II}|^n + C|\sigma_I - \sigma_{II}|^n \leq \sigma_0^n \quad (34)$$

244 can also be easily adapted from (33).

245 *3.5. A gallery of conic-representable strength criteria*

246 The `fenics_optim.limit_analysis` module provides access to a large class of usual strength criteria
 247 through the conic formulation of the criterion indicator and support functions, the latter being provided
 248 both in terms of strains and velocity discontinuities, see section 4. Table 1 provides a list of currently
 249 available material strength criteria.

Strength criterion	Mechanical model	Representation type
vonMises	2D/3D	SOC
DruckerPrager	2D/3D	SOC
Tresca2D	2D	SOC
MohrCoulomb2D	2D	SOC
Rankine2D	2D	SOC
Tresca3D	3D	SDP
MohrCoulomb3D	3D	SDP
Rankine3D	3D	SDP
TsaiWu	3D	SOC
Hosford	2D	Power

Table 1: List of available conic-representable strength criteria for 2D/3D continua

4. Finite-element limit analysis of 2D and 3D continua

In this section, we consider the standard continuum model where $\Sigma = \boldsymbol{\sigma}$ is the classical Cauchy symmetric stress tensor, \mathbf{u} a 2D or 3D velocity field and the associated strain is its symmetric gradient $\mathbf{D}\mathbf{u} = \nabla^s \mathbf{u}$. For simplicity, we will consider the case where there is no fixed loading $\mathbf{f}_0 = \mathbf{t}_0 = 0$.

4.1. Kinematic-based formulation

Let us now consider the finite-element discretization of the kinematic limit analysis approach (KA) for a continuous velocity field and imposed tractions on some part $\partial\Omega_T$ of the boundary:

$$\lambda^+ \leq \inf_{\mathbf{u} \in \mathcal{V}_h} \int_{\Omega} \pi_G(\nabla^s \mathbf{u}) \, dx \quad (35)$$

s.t. $\int_{\Omega} \mathbf{f} \cdot \mathbf{u} \, dx + \int_{\partial\Omega_T} \mathbf{t} \cdot \mathbf{u} \, dS = 1$

where \mathcal{V}_h is a finite-element subspace of Lagrange elements based on a given mesh of typical mesh size h . In the above problem, the computed objective function is an upper bound of the exact limit load factor λ^+ only if the integral of the objective function term is evaluated exactly. In general, this is not possible because of the non-linearity of function π_G , except in the special case of \mathbf{u} being interpolated with \mathbb{P}^1 -Lagrange elements so that the gradient is cell-wise constant and the integral becomes trivial.

As explained in [46], keeping an exact upper-bound estimate of λ^+ requires this integral to be estimated by excess. This is possible for a mesh consisting of simplex (straight edges) triangles and a \mathbb{P}^2 -Lagrange interpolation for \mathbf{u} when using the following so-called *vertex* quadrature scheme:

$$\int_T F(\mathbf{r}(\mathbf{x})) \, dx \lesssim \frac{|T|}{d+1} \sum_{i=1}^{d+1} F(\mathbf{r}(\mathbf{x}_i)) \quad (36)$$

where F is a convex function and \mathbf{r} is an affinely-varying function over the mesh cell T (either a triangle in dimension $d = 2$ or a tetrahedron for $d = 3$ of area/volume $|T|$) with $\mathbf{r}(\mathbf{x}_i)$ being its value at the $d+1$ -vertices. In this case, we have:

$$\lambda^+ \leq \lambda_u = \inf_{\mathbf{u} \in \mathcal{V}_h} \sum_{T \in \mathcal{T}_h} \frac{|T|}{d+1} \sum_{i=1}^{d+1} \pi_G(\nabla^s \mathbf{u}(\mathbf{x}_i)) \quad (37)$$

s.t. $\int_{\Omega} \mathbf{f} \cdot \mathbf{u} \, dx + \int_{\partial\Omega_T} \mathbf{t} \cdot \mathbf{u} \, dS = 1$

As discussed in [5], the `fenics.optim` package enables to solve convex variational problem of the form:

$$\inf_{\mathbf{u} \in \mathcal{V}} \int_{\Omega} (j_1 \circ \ell_1(\mathbf{u}) + \dots + j_p \circ \ell_p(\mathbf{u})) \, dx \quad (38)$$

s.t. $\mathbf{u} \in \mathcal{K}$

270 where j_i are conic-representable convex functions and ℓ_i are linear operators which can be expressed using UFL
 271 symbolic operators. Each individual term j_i can be specified independently along with its conic representation
 272 and the quadrature scheme used for the computation over Ω so that (38) is in fact of the form:

$$\begin{aligned} \inf_{\mathbf{u} \in \mathcal{V}} \quad & \sum_{i=1}^p \sum_{g_i=1}^{N_{g,i}} \omega_{g_i} j_i(\ell_i(\mathbf{u}; \mathbf{x}_{g_i})) \\ \text{s.t.} \quad & \mathbf{u} \in \mathcal{K} \end{aligned} \tag{39}$$

273 where $\ell_i(\mathbf{u}; \mathbf{x}_{g_i})$ denotes the evaluation of $\ell_i(\mathbf{u})$ at a quadrature point \mathbf{x}_{g_i} .

274 Local auxiliary variables \mathbf{y} of the conic representation (22) for each j_i will be added to the optimization
 275 problem for each quadrature point \mathbf{x}_{g_i} . More details can be found in [5].

276
 277 Obviously, problem (35) is a problem of the form (38) in which $j_1 = \pi_G$, $\ell_1 = \nabla^s$ and j_2 is the indi-
 278 cator function of the linear constraint $\int_{\Omega} \mathbf{f} \cdot \mathbf{u} \, dx + \int_{\partial\Omega_T} \mathbf{t} \cdot \mathbf{u} \, dS = 1$ with ℓ_2 being the identity. Ignoring
 279 import statements and mesh generation, we now give a few lines of Python script to illustrate how the
 280 `fenics_optim.limit_analysis` module enables to formulate an upper bound limit analysis problem for a
 281 2D Mohr-Coulomb material using a \mathbb{P}^2 -Lagrange interpolation for $\mathbf{u} \in \mathcal{V}_h$. First, the corresponding function
 282 space \mathbf{V} is defined and fixed boundary conditions are imposed on the part named "border" of the boundary.
 283 A `MosekProblem` object is instantiated and a first optimization field \mathbf{u} belonging to function space \mathbf{V} is added
 284 to the problem and is constrained to satisfy the Dirichlet boundary conditions:

```
1 V = VectorFunctionSpace(mesh, "CG", 2)
2 bc = DirichletBC(V, Constant((0., 0.)), border)
3
4 prob = MosekProblem("Upper bound limit analysis")
5 u = prob.add_var(V, bc=bc)
```

285 The external work normalization constraint is then added by defining the function space for the Lagrange
 286 multiplier corresponding to the constraint (here it is scalar so we use a "Real" function space) and passing
 287 the corresponding constraint in its weak form as follows (here $\mathbf{t} = 0$):

```
1 R = FunctionSpace(mesh, "R", 0)
2 def Pext(lamb):
3     return [lamb*dot(f, u)*dx]
4 prob.add_eq_constraint(R, A=Pext, b=1)
```

288 Now, a Mohr-Coulomb material is instantiated and provides access to its convex support function. The input
 289 arguments are the strain $\nabla^s \mathbf{u}$ written in terms of UFL operators as well as the choice for the quadrature
 290 scheme used for its numerical evaluation. Here the *vertex* scheme (36) is chosen. This convex function is
 291 then added to the problem before asking for its optimization by `Mosek`.

```
1 mat = MohrCoulomb2D(c, phi)
2 strain = sym(grad(u))
3 pi = mat.support_function(strain, quadrature_scheme="vertex")
4 prob.add_convex_term(pi)
5
6 prob.optimize()
```

292 4.2. Static-based formulation

293 Conversely, a lower bound estimate of the limit load factor λ^+ can be obtained by considering a statically
 294 admissible discretization of the stress field $\boldsymbol{\sigma}$. For this purpose, we consider the lower bound element of
 295 [44, 64], which includes statically admissible discontinuities between facets. The problem we aim at solving

296 is the following:

$$\begin{aligned}
 \lambda^+ \geq \lambda_s = \sup_{\lambda \in \mathbb{R}, \boldsymbol{\sigma} \in \mathcal{W}_h} \lambda \\
 \text{s.t.} \quad & \operatorname{div} \boldsymbol{\sigma} + \lambda \mathbf{f} = 0 \quad \text{in } \Omega \\
 & [[\boldsymbol{\sigma}]] \cdot \mathbf{n} = 0 \quad \text{through } \Gamma \\
 & \boldsymbol{\sigma} \cdot \mathbf{n} = \lambda \mathbf{t} \quad \text{on } \partial\Omega_T \\
 & \boldsymbol{\sigma}(\mathbf{x}) \in G \quad \forall \mathbf{x} \in \Omega
 \end{aligned} \tag{40}$$

297 where Γ is the set of internal facets and $[[\boldsymbol{\sigma}]]$ the stress discontinuity across this facet of normal \mathbf{n} .

298

299 For this problem, we have as optimization variables one real λ and a discontinuous piecewise-linear field
 300 $\boldsymbol{\sigma}$ represented by a vector of dimension 3 in 2D (6 in 3D), \mathcal{W}_h being the associated discontinuous \mathbb{P}_d^1 function
 301 space:

```

1 prob = MosekProblem("Lower bound limit analysis")
2 R = FunctionSpace(mesh, "R", 0)
3 W = VectorFunctionSpace(mesh, "DG", 1, dim=3)
4 lamb, Sig = prob.add_var([R, W])
5 sig = as_matrix([[Sig[0], Sig[2]],
6                 [Sig[2], Sig[1]]])

```

302 Assuming piecewise constant body force over each cell, the first local equilibrium equation can be equiv-
 303 alently written weakly using \mathbb{P}^0 velocity fields as Lagrange multipliers:

```

1 V_eq = VectorFunctionSpace(mesh, "DG", 0)
2 def equilibrium(u):
3     return [dot(u, f)*lamb*dx, dot(u, div(sig))*dx]
4 prob.add_eq_constraint(V_eq, A=equilibrium)

```

304 Note that in the `equilibrium` function each block respectively corresponds to the optimization variable λ
 305 then $\boldsymbol{\sigma}$, in the order they have been initially defined. See more details in [5] on the underlying block-structure
 306 of the problem.

307 Similarly, discontinuous affine displacements \mathbf{v} defined on the mesh facets only¹ are used as Lagrange
 308 multipliers for the second and third constraints (here $\mathbf{t} = 0$):

```

1 V_jump = VectorFunctionSpace(mesh, "Discontinuous Lagrange Trace", 1)
2 def continuity(v):
3     return [None, dot(avg(v), jump(sig, n))*dS
4             + dot(v, dot(sig, n))*ds(0)]
5 prob.add_eq_constraint(V_jump, A=continuity)

```

309 where the `dS` term corresponds to the integral over all internal facets Γ and `ds(0)` corresponds to the integral
 310 over $\partial\Omega_T$ in this case.

311 Finally, the problem objective function is added to the problem as well as the strength criterion condition.
 312 The latter is treated as a convex function through its indicator function. A quadrature scheme is still needed
 313 since quadrature points will correspond to points at which the strength condition will be enforced. In the
 314 present case, the *vertex* scheme will enforce the strength condition at the triangle vertices so that it will be
 315 satisfied everywhere inside the cell by convexity. The maximization problem is then solved by `Mosek`:

```

1 prob.add_obj_func([1, None])
2
3 crit = mat.criterion(Sig, quadrature_scheme="vertex")
4 prob.add_convex_term(crit)
5
6 prob.optimize(sense="maximize")

```

¹They are called `Discontinuous Lagrange Trace` elements in FEniCS

316 Note that Mosek solutions give access to dual variables (Lagrange multipliers) so that a pseudo velocity
 317 field can be obtained from \mathbf{u} for instance.

318 4.3. Mixed finite-element discretizations

319 The kinematic formulation (35) is sometimes difficult to use because the support function expression may
 320 be cumbersome to derive. As a result, a static-based formulation as in (40) is usually more attractive as it
 321 requires only the expression of the strength criterion itself. Formulation (7) enables to produce upper bounds
 322 equivalent to (35), provided a proper choice of interpolation spaces for \mathbf{u} and $\boldsymbol{\Sigma}$ and quadrature rules. In the
 323 general case, such a formulation forms the basis of mixed finite-element interpolations for which the bounding
 324 status is lost in general [14, 1, 15, 18]. This formulation reads here as:

$$\begin{aligned} \lambda_m = \sup_{\lambda \in \mathbb{R}, \boldsymbol{\sigma} \in \mathcal{W}_h} \lambda \\ \text{s.t.} \quad \int_{\Omega} \boldsymbol{\sigma} : \nabla^s \mathbf{u} \, dx = \lambda \left(\int_{\Omega} \mathbf{f} \cdot \mathbf{u} \, dx + \int_{\partial\Omega_T} \mathbf{t} \cdot \mathbf{u} \, dS \right) \quad \forall \mathbf{u} \in \mathcal{V}_h \\ \boldsymbol{\sigma}(\mathbf{x}) \in G \quad \forall \mathbf{x} \in \Omega \end{aligned} \quad (41)$$

325 in which the static equilibrium conditions have been replaced by their weak counterpart using the virtual
 326 work principle for a class of kinematically admissible continuous velocity fields $\mathbf{u} \in \mathcal{V}_h$. As mentioned in [5],
 327 if \mathcal{V}_h corresponds to a continuous \mathbb{P}^1 -Lagrange interpolation, \mathcal{W}_h to a discontinuous \mathbb{P}^0 interpolation of the
 328 stress field and the strength criterion is enforced at one point in each cell (this is enough since $\boldsymbol{\sigma}$ is cell-wise
 329 constant), then (41) is equivalent, it is even the dual problem, to (35) for the same \mathcal{V}_h .

330 For other cases, such as \mathcal{V}_h being \mathbb{P}^2 -Lagrange and \mathcal{W}_h discontinuous \mathbb{P}^1_d -Lagrange, quadrature rules must
 331 be specified both for the equilibrium constraint as well as for the strength criterion (criterion enforcement
 332 points). If both quadrature rules are identical, then problem (41) is equivalent to problem (35) for the chosen
 333 quadrature rule. Upon choosing a vertex scheme, the objective value λ_m will be an upper-bound to λ^+ . Other
 334 choices such as quadrature points located at the mid-side points do not produce rigorous upper bounds but
 335 are usually observed to converge from above in practice. When both quadrature rules are different, one
 336 obtains a true mixed-interpolation and again the bounding status is lost.

337 The FEniCS formulation for the first case $\mathbb{P}^1/\mathbb{P}^0$ for $\mathcal{V}_h/\mathcal{W}_h$ would read as (here quadrature rules are
 338 trivial one-point rules by default):

```

1  prob = MosekProblem("Upper bound from static formulation")
2  R = FunctionSpace(mesh, "R", 0)
3  W = VectorFunctionSpace(mesh, "DG", 0, dim=3)
4  lamb, Sig = prob.add_var([R, W])
5
6  V = VectorFunctionSpace(mesh, "CG", 1)
7  bc = DirichletBC(V, Constant((0, 0)), border)
8
9  sig = as_matrix([[Sig[0], Sig[2]],
10                 [Sig[2], Sig[1]]])
11  def equilibrium(u):
12      return [lamb*dot(u, f)*dx, -inner(sig, sym(grad(u)))*dx]
13  prob.add_eq_constraint(V, A=equilibrium, bc=bc)
14
15  prob.add_obj_func([1, None])
16
17  crit = mat.criterion(Sig)
18  prob.add_convex_term(crit)
19
20  prob.optimize(sense="maximize")

```

339 4.4. Discontinuous velocity fields

340 As mentioned in the introduction, the use of discontinuous velocity fields is interesting in a limit analysis
341 context due to a higher accuracy and the absence of volumetric or shear locking effects.

342 In case of discontinuous velocity fields across a set Γ of discontinuity surfaces, the kinematic limit analysis
343 formulation (35) now becomes:

$$\lambda^+ \leq \lambda_u = \inf_{\mathbf{u} \in \mathcal{V}_h} \int_{\Omega} \pi_G(\nabla^s \mathbf{u}) \, dx + \int_{\Gamma} \Pi_G(\llbracket \mathbf{u} \rrbracket; \mathbf{n}) \, dS \quad (42)$$

s.t. $\int_{\Omega} \mathbf{f} \cdot \mathbf{u} \, dx + \int_{\partial\Omega_T} \mathbf{t} \cdot \mathbf{u} \, dS = 1$

344 where the second term of the objective function denotes the dissipated power contribution of the velocity
345 jumps $\llbracket \mathbf{u} \rrbracket$ through a surface Γ of normal \mathbf{n} . It is computed from the discontinuity support function:

$$\Pi_G(\mathbf{v}; \mathbf{n}) = \sup_{\boldsymbol{\sigma} \in G} \{(\boldsymbol{\sigma} \cdot \mathbf{n}) \cdot \mathbf{v}\} = \pi_G(\mathbf{v} \overset{s}{\otimes} \mathbf{n}) \quad (43)$$

346 i.e. the jump operator is here $\mathbf{J}\mathbf{u} = \llbracket \mathbf{u} \rrbracket \overset{s}{\otimes} \mathbf{n}$. As a result, the second term will also be conic-representable and
347 will be treated similarly. Despite this relation, the conic representation of $\Pi_G(\mathbf{v}; \mathbf{n})$ is usually implemented
348 explicitly in the material library due to the potential savings in terms of auxiliary variables compared to calling
349 directly $\pi_G(\mathbf{v} \overset{s}{\otimes} \mathbf{n})$. A local projection of $\llbracket \mathbf{u} \rrbracket$ on the facet (\mathbf{n}, \mathbf{t}) -plane is performed as Π_G functions are in
350 general naturally expressed in this local frame. Finally, adding the discontinuity term to the optimization
351 problem is similar to the first term, one must just specify the integration measure (the inner facets) and the
352 quadrature rule which must be used to perform the facet integration.

353 4.5. Mesh refinement

354 For improving the quality of the computed limit load estimates, a mesh refinement procedure is also
355 implemented based on the contribution of each cell to maximum resisting work $\mathcal{P}^{(mr)}$ in the context of a
356 kinematic approach. The cell contributions are sorted in descending order and we compute the cumulated
357 contribution to $\mathcal{P}^{(mr)}$ until reaching a user-specified threshold $\eta \mathcal{P}^{(mr)}$ (with a ratio η of 0.5 typically) of
358 the total dissipation. The first k cells whose total contribution is at least $\eta \mathcal{P}^{(mr)}$ are then marked for mesh
359 refinement. In the case of discontinuous elements, the facet contribution to $\mathcal{P}^{(mr)}$ is computed for each facet,
360 split evenly between the two sharing cells and added to the cell contributions. For the lower bound approach,
361 a similar procedure is used except that we use the dual variable associated with the local equilibrium equation
362 to reconstruct a piecewise linear velocity field from which we compute a cell-wise contribution to the total
363 dissipation.

364 4.6. Vertical cut-off stability

365 The different discretization choices are illustrated on the stability of a vertical slope under its self-weight
366 γ . The rectangular domain, of height H , is clamped on both bottom and left boundaries and traction-free
367 on the remaining boundaries (see Figure 1-right). The soil is modelled as a Mohr-Coulomb material with
368 cohesion c and friction angle $\phi = 30^\circ$ under plane strain conditions. The slope factor of safety is given by
369 the maximum value of the non-dimensional quantity $(\gamma H/c)^+$. Convergence of the factor of safety estimates
370 for various finite-element discretizations are reported on Figure 1-left as a function of the total number of
371 elements, the concentration of the local dissipation $\pi_G(\nabla^s \mathbf{u})$ along the slip-line is represented on Figure
372 1-right. The comparison between continuous and discontinuous upper bound finite elements is reported in
373 Figure 2. Similarly, the comparison between uniform and adaptive mesh refinement is reported in Figure 3
374 along with the final adapted mesh.

375 In order to assess the computational effort required for solving this problem, problem statistics as well
376 as optimization computing times have been reported in Table 2 for the lower-bound (LB) element and the
377 quadratic upper-bound (UB2) element for various mesh sizes (uniform mesh refinement). It can be observed
378 that, for the same mesh size, the lower-bound element involves more optimization variables (including auxil-
379 iary variables involved in the conic reformulation) than the upper-bound element. However, total optimization
380 times are comparable between both approaches, most likely due to a smaller number of iterations required
381 to reach convergence with the lower-bound element. Interestingly, the computing time scales almost linearly
382 with the number of elements.

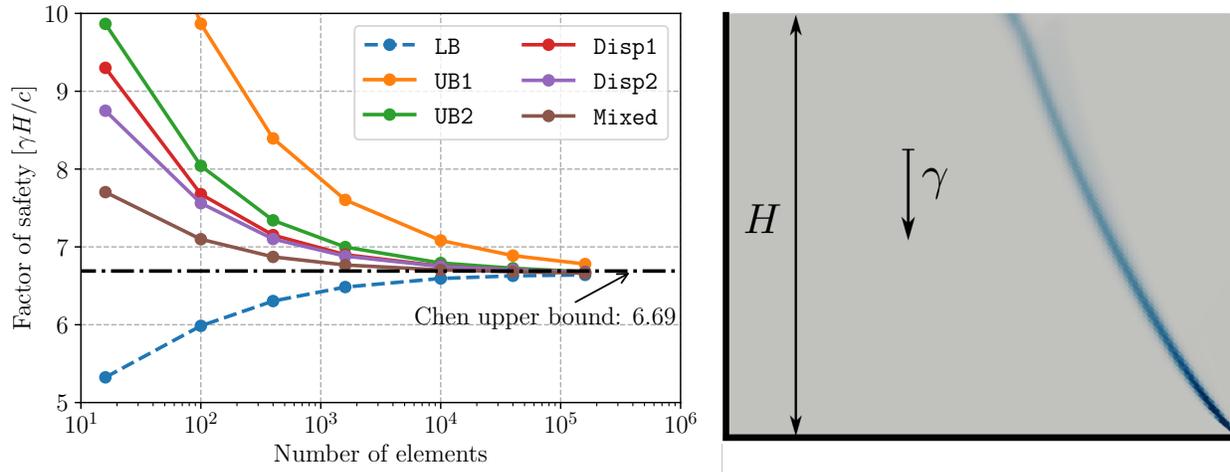

Figure 1: Left: Convergence of the vertical slope factor of safety for various finite element discretization: UB1 (resp. UB2) are the \mathbb{P}^1 (resp. \mathbb{P}^2) Lagrange upper bound elements, LB the lower bound element and Disp1, Disp2, Mixed correspond to non-upper bound elements considered in [37]. Analytical upper bound from Chen [17]. Right: local dissipation map

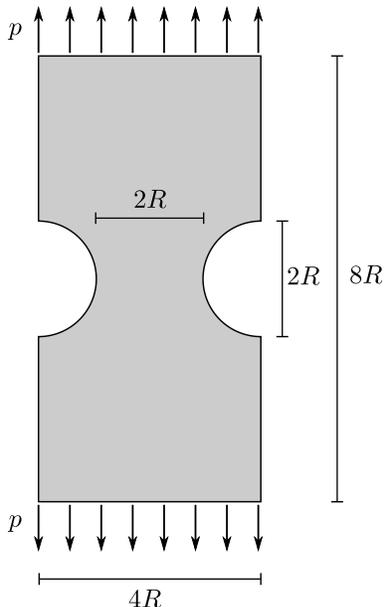

Figure 4: Grooved plate under tension

383 4.7. Tensile strength of a grooved metallic plate

384 We consider here the problem of a grooved rectangular plate made (see Figure 4) of a metallic material
 385 obeying the Hosford criterion in plane-stress conditions. This problem has been previously investigated
 386 analytically or numerically using the von Mises and Tresca criterion. For the Tresca criterion, the exact
 387 analytical solution is known to be $p^+ = 0.5\sigma_0$. For the von Mises criterion, a simple upper-bound obtained
 388 from the Tresca solution is $p^+ \leq \sigma_0/\sqrt{3} \approx 0.577\sigma_0$ whereas various more accurate numerical estimates are
 389 reported in [54]. Most of them seem to estimate $p^+ \approx 0.558\sigma_0$ such as [68].

390 We computed the corresponding estimates in the case of Hosford material using the power-cone formula-
 391 tion (33) and a kinematic approach using \mathbb{P}^2 -elements (we relied on a static-based formulation as discussed
 392 in section 4.3). The evolution of the computed limit load as a function of the Hosford exponent n has been
 393 reported in Figure 5. As expected, we retrieve the von Mises numerical estimate of [68] in the case $p = 2$ and
 394 the Tresca solution $p^+ = 0.5\sigma_0$ when n is approaching 1 and $+\infty$. For all values of n , the IPM algorithm of
 395 Mosek v.9 exhibited good convergence properties, requiring an average of 36 s of optimization (35 iterations)
 396 for a problem involving approximately 350,000 optimization variables and 250,000 linear constraints (mesh
 397 of 8047 elements). However, it must be noted that solving directly a plane-stress von Mises problem using
 398 a single second-order cone constraint on the same mesh ($N_{\text{var}} = 170,000$ and $N_{\text{con}} = 130,000$) requires only
 399 5 s (13 iterations). Using a finer mesh yielding a similar number of variables and constraints as the Hosford
 400 problem required less than 8 s. As a result, even though power-cone constraints are now available and can be
 401 solved in reasonable times, the computational effort is still larger than for SOCP problems, even for problems
 402 of similar sizes.

403 5. Computation of macroscopic strength properties through homogenization theory

404 In this section, we show how to adapt the above-described framework to compute macroscopic strength
 405 properties of heterogeneous materials. Indeed, limit analysis can be combined to homogenization theory
 406 [66, 13] to compute macroscopic strength criteria of heterogeneous materials by solving an auxiliary limit
 407 analysis problem formulated on a representative elementary volume or a periodic unit-cell for periodically het-
 408 erogeneous materials. We will consider here the latter case and denote \mathcal{A} the unit cell domain. The strength
 409 conditions are described by a spatially varying strength criterion $G(\mathbf{x})$. The main goal of homogenization in

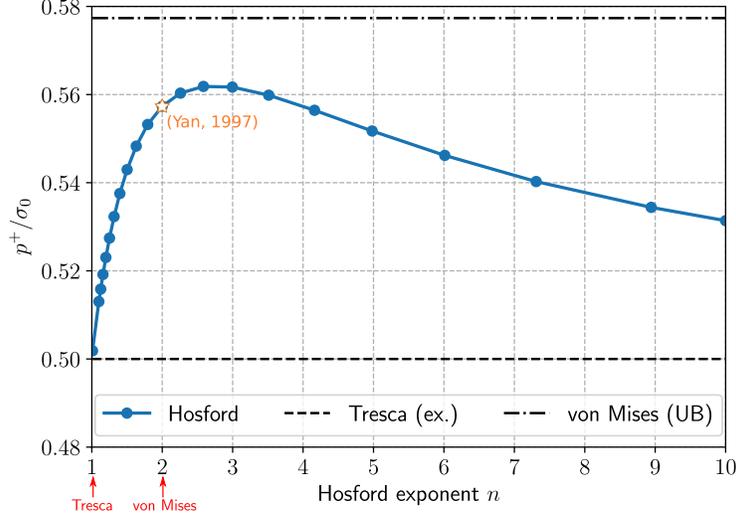

Figure 5: Limit load of the grooved plate example using a Hosford material of exponent n . The case $n = 2$ corresponds to the von Mises criterion with the numerical solution $p^+ \approx 0.558\sigma_0$ from [68].

410 limit analysis is to compute the macroscopic strength domain G^{hom} defined as follows:

$$\Sigma \in G^{hom} \iff \begin{cases} \operatorname{div} \boldsymbol{\sigma} = 0 & \text{in } \mathcal{A} \\ \llbracket \boldsymbol{\sigma} \rrbracket \cdot \mathbf{n} = 0 & \text{through } \Gamma \\ \boldsymbol{\sigma} \cdot \mathbf{n} & \text{antiperiodic} \\ \boldsymbol{\sigma}(\mathbf{x}) \in G(\mathbf{x}) & \forall \mathbf{x} \in \mathcal{A} \\ \frac{1}{|\mathcal{A}|} \int_{\mathcal{A}} \boldsymbol{\sigma} \, dx = \Sigma \end{cases} \quad (44)$$

411 Upon choosing a given loading direction Σ_0 of arbitrary magnitude, one can look for an estimate to the
 412 maximum load factor λ^+ such that $\lambda^+ \Sigma_0 \in G^{hom}$, yielding the following maximization problem:

$$\lambda^+ \geq \lambda_s = \sup_{\lambda \in \mathbb{R}, \boldsymbol{\sigma} \in \mathcal{W}_h} \lambda \quad \text{s.t.} \quad \begin{cases} \operatorname{div} \boldsymbol{\sigma} = 0 & \text{in } \mathcal{A} \\ \llbracket \boldsymbol{\sigma} \rrbracket \cdot \mathbf{n} = 0 & \text{through } \Gamma \\ \boldsymbol{\sigma} \cdot \mathbf{n} & \text{antiperiodic} \\ \boldsymbol{\sigma}(\mathbf{x}) \in G(\mathbf{x}) & \forall \mathbf{x} \in \mathcal{A} \\ \frac{1}{|\mathcal{A}|} \int_{\mathcal{A}} \boldsymbol{\sigma} \, dx = \lambda \Sigma_0 \end{cases} \quad (45)$$

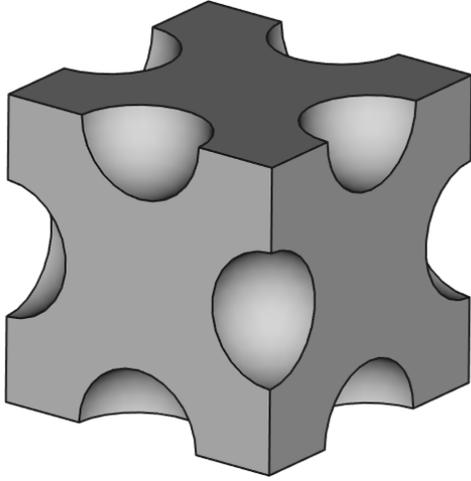

413 Definition (45) correspond to the static formulation of a limit analysis problem formulated on \mathcal{A} with
 414 loading being parametrized by Σ_0 . Its dual counter-part (kinematic formulation) can be shown to be given
 415 by²:

$$\lambda^+ \leq \lambda_u = \inf_{\mathbf{D} \in \mathbb{R}^6, \mathbf{u} \in \mathcal{V}_h} \int_{\Omega} \pi(\mathbf{D} + \nabla^s \mathbf{u}; \mathbf{x}) \, dx \quad \text{s.t.} \quad \begin{cases} |\mathcal{A}| \Sigma_0 : \mathbf{D} = 1 \\ \mathbf{u} \text{ periodic} \end{cases} \quad (46)$$

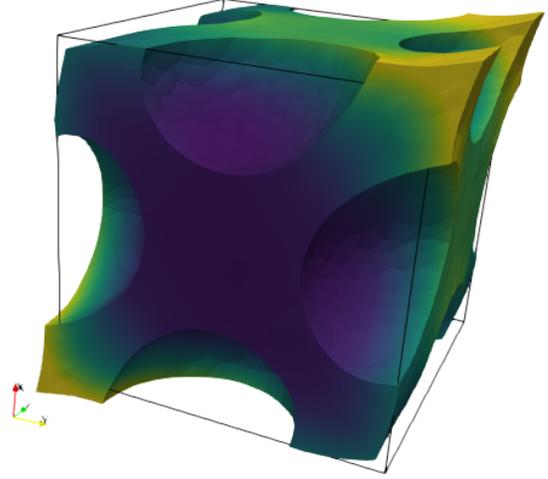

416 Let us remark that:

$$\Pi_{hom}(\mathbf{D}) = \lambda^+ \Sigma_0 : \mathbf{D} \leq \frac{1}{|\mathcal{A}|} \int_{\Omega} \pi(\mathbf{D} + \nabla^s \mathbf{u}; \mathbf{x}) \, dx \quad (47)$$

²This formulation can obviously be easily extended to take into account discontinuous velocity fields.

(a) Porous 3D medium unit cell

(b) Unit-cell response to a pure-shear loading

Figure 6: Homogenization of a 3D porous medium

417 where $\Pi_{hom}(\mathbf{D}) := \sup_{\Sigma \in G^{hom}} \{\Sigma : \mathbf{D}\}$ is the macroscopic support function.

418 In (46), the macroscopic strain is considered as an additional optimization variable since the loading
 419 direction Σ_0 is fixed. It is also possible to prescribe directly the macroscopic strain direction \mathbf{D} , leaving free
 420 the loading direction, by removing the first constraint in (46).

421

422 Formulation (46) is applied to a 3D periodic porous medium with pores following a face-centered cubic
 423 system (see Figure 6a) made of a Drucker-Prager material ($c = 1, \phi = 30^\circ$). The unit cell response $\mathbf{U}(\mathbf{x}) =$
 424 $\mathbf{D} \cdot \mathbf{x} + \mathbf{u}(\mathbf{x})$ to a pure shear loading $\Sigma_{xy,0} = 1$ is represented on Figure 6b. The macroscopic strength domain
 425 in the $(\Sigma_{xx}, \Sigma_{yy})$ plane and in the $(\Sigma_{xx}, \Sigma_{xy})$ with other $\Sigma_{ij} = 0$ have been represented on Figure 7. It can
 426 be observed how much the presence of the pores reduces the original Drucker-Prager criterion of the skeleton.

427 6. Plates and shells

428 6.1. Thin and thick plates

429 In this section, we show how limit analysis of thin and thick plates can be tackled by following exactly the
 430 general format described in section 2 and implemented easily by taking advantage of the high-level symbolic
 431 representation of operators in FEniCS. First, let us recall that the kinematic limit analysis of thin plates
 432 obeying a Love-Kirchhoff kinematics corresponds to the following minimization problem:

$$\begin{aligned}
 & \inf_w \int_{\Omega} \pi_G(\nabla^2 w) \, dx + \int_{\Gamma} \Pi_G([\partial_n w] \mathbf{n}; \mathbf{n}) \, dS \\
 & \text{s.t.} \quad \int_{\Omega} f w \, dx = 1
 \end{aligned} \tag{48}$$

433 for a distributed loading f . It can be seen that (48) complies with (KA) where the generalized velocity is
 434 only the virtual deflection w , the strain operator is the curvature $\mathbf{D}u = \nabla^2 w$ and the velocity jump is
 435 given by a normal rotation jump $\mathbf{J}u = [\partial_n w] \mathbf{n} \otimes \mathbf{n}$. In the above, π_G and Π_G are the support functions
 436 of the corresponding thin plate strength criterion G_{bend} , expressed solely on the bending moment tensor

437 $\mathbf{M} = \begin{bmatrix} M_{xx} & M_{xy} \\ M_{xy} & M_{yy} \end{bmatrix}$ with $\Pi_G([\partial_n w] \mathbf{n}; \mathbf{n}) = \pi_G([\partial_n w] \mathbf{n} \otimes \mathbf{n})$. As a result, thin plate strength criteria and

438 their support functions are treated exactly as 2D continua with the only difference coming from the definition
 439 of the strain and discontinuity operators. We refer to [5] for an implementation example of thin plate limit
 440 analysis using the `fenics.optim` package. Let us also remark that implementing the corresponding lower

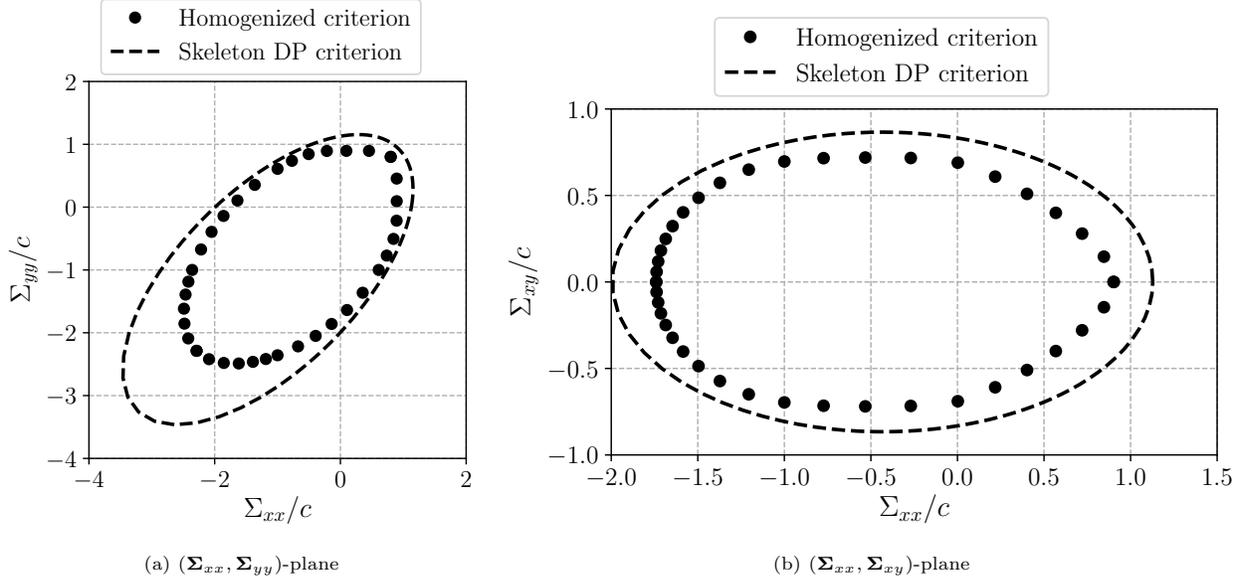

Figure 7: Homogenized strength criterion

bound static approach is more involved due to the more complicated continuity conditions involving equivalent Kirchhoff shear forces (see [34, 7]).

As regards thick plates involving shear and bending strength conditions and following Reissner-Mindlin kinematics, the main difference with respect to 2D/3D continua or thin plates is that two unknown fields must be considered instead of one: bending moments \mathbf{M} and shear forces $\mathbf{Q} = (Q_x, Q_y)$ for the static approach and out-of-plane deflection w and plate rotations $\boldsymbol{\theta} = (\theta_x, \theta_y)$ for the kinematic approach. We now discuss only the latter since the former will be discussed in the more general case of shells in the next subsection. Following [10], kinematic limit analysis of thick plates can be written as:

$$\begin{aligned} \inf_{w, \boldsymbol{\theta}} \quad & \int_{\Omega} \pi_G((\nabla \boldsymbol{\theta}, \nabla w - \boldsymbol{\theta})) \, dx + \int_{\Gamma} \Pi_G(([\boldsymbol{\theta}], [w]); \mathbf{n}) \, dS \\ \text{s.t.} \quad & \int_{\Omega} f w \, dx = 1 \end{aligned} \quad (49)$$

Again, the structure is the same as before with $\mathbf{u} = (w, \boldsymbol{\theta})$, the (generalized) strain $\mathbf{D}\mathbf{u} = (\boldsymbol{\chi}, \boldsymbol{\gamma})$ consisting of the curvature $\boldsymbol{\chi} = \nabla \boldsymbol{\theta}$ and the shear strain $\boldsymbol{\gamma} = \nabla w - \boldsymbol{\theta}$. In the above, the support functions π_G and Π_G are defined with respect to a thick plate strength criterion involving both the bending moment tensor \mathbf{M} and the shear force vector \mathbf{Q} i.e. $\boldsymbol{\Sigma} = (\mathbf{M}, \mathbf{Q})$. In [8, 10], different choices of thick plate criteria are discussed, especially regarding the bending/shear interaction. For the sake of simplicity, we consider here only the case of no interaction between bending and shear, meaning that the thick plate strength criterion is in fact decoupled between bending and shear, taking the following form:

$$(\mathbf{M}, \mathbf{Q}) \in G_{\text{thick plate}} \iff \begin{cases} \mathbf{M} \in G_{\text{bend}} \\ \mathbf{Q} \in G_{\text{shear}} \end{cases} \quad (50)$$

where typically $G_{\text{shear}} = \{\mathbf{Q} \text{ s.t. } \|\mathbf{Q}\|_2 \leq Q_0\}$ with Q_0 being the plate pure shear strength. Since typical thin plate criteria are SOC-representable, so will be the thick plate criterion (50). We also have the following expression for the corresponding support function:

$$\begin{aligned} \pi_{G_{\text{thick plate}}}((\boldsymbol{\chi}, \boldsymbol{\gamma})) &= \sup_{(\mathbf{M}, \mathbf{Q}) \in G_{\text{thick plate}}} \{\mathbf{M} : \boldsymbol{\chi} + \mathbf{Q} \cdot \boldsymbol{\gamma}\} \\ &= \sup_{\mathbf{M} \in G_{\text{bend}}} \{\mathbf{M} : \boldsymbol{\chi}\} + \sup_{\mathbf{Q} \in G_{\text{shear}}} \{\mathbf{Q} \cdot \boldsymbol{\gamma}\} \\ &= \pi_{G_{\text{bend}}}(\boldsymbol{\chi}) + \pi_{G_{\text{shear}}}(\boldsymbol{\gamma}) \end{aligned} \quad (51)$$

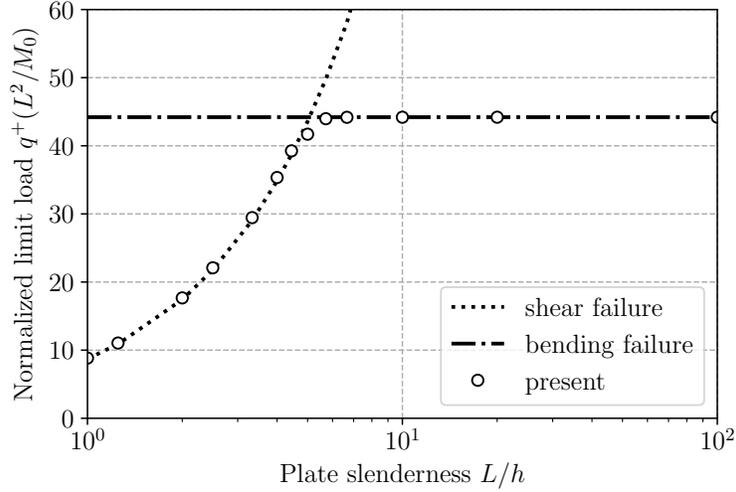

Figure 8: Normalized limit load $q^+ L^2/M_0$ of a square clamped plate as function of plate slenderness L/h : comparison with pure shear and pure bending failure mechanisms

456 with $\pi_{G_{\text{shear}}}(\boldsymbol{\gamma}) = Q_0 \|\boldsymbol{\gamma}\|_2$ and $\pi_{G_{\text{bend}}}$ depending on the choice of the bending strength criterion. Finally, the
 457 (generalized) velocity jump consisting of the rotation and velocity jumps $\mathbf{J}\mathbf{u} = ([\boldsymbol{\theta}] \stackrel{s}{\otimes} \mathbf{n}, [w]\mathbf{n})$ so that we
 458 also have:

$$\Pi_G([\boldsymbol{\theta}], [w]; \mathbf{n}) = \pi_G([\boldsymbol{\theta}] \stackrel{s}{\otimes} \mathbf{n}, [w]\mathbf{n}) \quad (52)$$

459 As discussed in [10], finite-element discretization for the upper bound limit analysis of thick plates must be
 460 chosen with care. Indeed, continuous Lagrange interpolations for both the deflection w and the rotation field $\boldsymbol{\theta}$
 461 will exhibit shear locking in the thin plate limit. Reference [10] considered fully discontinuous interpolation of
 462 both fields and showed extremely good performances. To illustrate the versatility of the proposed framework,
 463 we consider here a small variant, namely a continuous \mathbb{P}^2 -Lagrange interpolation for the deflection w and
 464 a discontinuous \mathbb{P}_d^1 -Lagrange interpolation for the rotation $\boldsymbol{\theta}$. This interpolation choice is expected to yield
 465 similar performances, although slightly higher, as the fully discontinuous $\mathbb{P}_d^2/\mathbb{P}_d^1$ interpolation of [10]. The
 466 problem of a uniformly distributed (intensity q) clamped square plate of side length L and thickness h is
 467 considered with a von Mises bending strength criterion (bending strength $M_0 = \sigma_0 h^2/4$). The shear strength
 468 is taken as $Q_0 = \sigma_0 h/\sqrt{3}$. As already observed in [8, 10], for the case of no bending/shear interaction, the
 469 limit load for this problem is well approximated by:

$$q^+ = \min\{q_{\text{shear}}^+; q_{\text{bending}}^+\} \quad (53)$$

470 where $q_{\text{shear}}^+ = (2 + \sqrt{\pi})Q_0/L$ is the pure shear solution for a square plate (see the Cheeger set example of
 471 [5]) and $q_{\text{bending}}^+ \approx 44.2M_0/L^2$ is the pure bending thin plate solution. This is indeed what is also observed
 472 for the present interpolation with a 50×50 mesh, see Figure 8. The correct pure shear (Figure 9) and pure
 473 bending (Figure 10) mechanisms are also retrieved.

474 6.2. Shells and multilayered plates

Let us now briefly consider the case of shells, for which we will discuss here a lower bound implementation only. We refer to [9] and references therein for more details concerning limit analysis of shells, especially the upper bound kinematic approach. The shell geometry will be approximated by a plane facet discretization into triangular elements and will be described locally by a unit normal $\boldsymbol{\nu}$ and a tangent plane spanned by two unit vectors \mathbf{a}_1 and \mathbf{a}_2 . This local frame is therefore constant element-wise. The generalized internal forces of the shell model are described by a symmetric *membrane force* tensor $\mathbf{N} = N_{ij}\mathbf{a}_i \otimes \mathbf{a}_j$, a symmetric *bending moment* tensor $\mathbf{M} = M_{ij}\mathbf{a}_i \otimes \mathbf{a}_j$ and a *shear force* vector $\mathbf{Q} = Q_i\mathbf{a}_i$ ($i, j = 1, 2$), the components of which are expressed in the local tangent plane. We will consider only thin shells, meaning that the shell strength

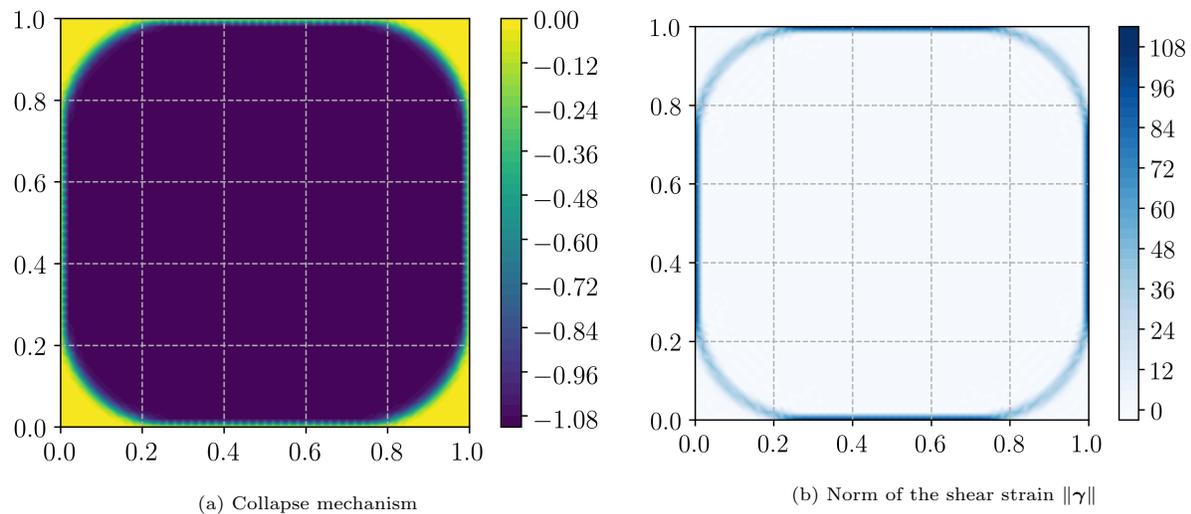

Figure 9: Pure shear collapse solution for a thick plate ($h/L = 0.5$)

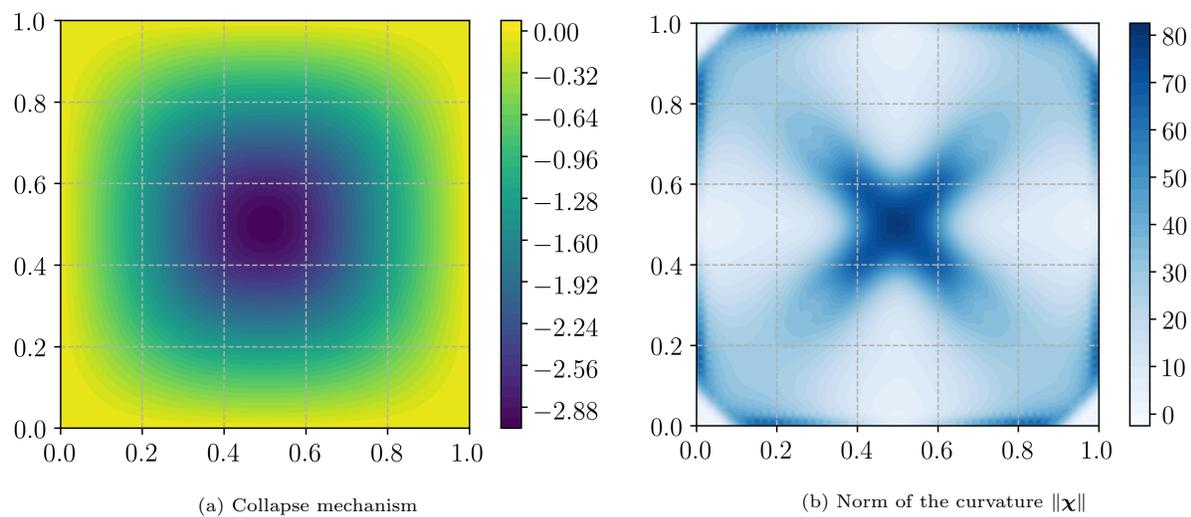

Figure 10: Pure bending collapse solution for a thin plate ($h/L = 0.01$)

criterion G_{shell} is a convex set in the 6-dimensional (\mathbf{N}, \mathbf{M}) space (infinite shear strength assumption). Introducing $\mathbf{T} = \mathbf{N} + \boldsymbol{\nu} \otimes \mathbf{Q}$, the local equilibrium equations in a plane facet are given by:

$$\text{div}_T \mathbf{T} + \lambda \mathbf{f} = 0 \quad (54)$$

$$\text{div}_T \mathbf{M} + \mathbf{Q} = 0 \quad (55)$$

where div_T is the tangent plane divergence operator and $\lambda \mathbf{f}$ a distributed loading with an amplification factor λ . In addition to local equilibrium, continuity equations of the force resultant $\mathbf{R} = \mathbf{T} \cdot \mathbf{n}$ and the normal bending moment $\mathcal{M} = \mathbf{M} \cdot \mathbf{n} \times \boldsymbol{\nu}$ must be satisfied where \mathbf{n} is the in-plane normal to a facet edge:

$$\llbracket \mathbf{R} \rrbracket = 0 \quad (56)$$

$$\llbracket \mathcal{M} \rrbracket = 0 \quad (57)$$

475 Finite-element discretization relies on a discontinuous \mathbb{P}_d^1 interpolation for both membrane forces \mathbf{N} and
 476 shear forces \mathbf{Q} and a discontinuous \mathbb{P}_d^2 interpolation for the bending moments \mathbf{M} . Considering cell-wise
 477 uniform distributed loadings, local force equilibrium (54) is uniform and can therefore be satisfied exactly
 478 using a cell-wise constant Lagrange multiplier \mathbf{u} . Local moment equilibrium (55) can be satisfied exactly using
 479 a cell-wise linear Lagrange multiplier $\boldsymbol{\theta}$. Force and moment continuity equations (56)-(57) are respectively
 480 satisfied by considering facet-wise linear and quadratic Lagrange multipliers \mathbf{v} and $\boldsymbol{\vartheta}$. We again give below
 481 the main part of the corresponding Python code for formulating this rather complex problem:

```

1  prob = MosekProblem("Shell lower bound limit analysis")
2  R = FunctionSpace(mesh, "R", 0)
3  Ne = VectorElement("DG", mesh.ufl_cell(), 1, dim=3)
4  Me = VectorElement("DG", mesh.ufl_cell(), 2, dim=3)
5  Qe = VectorElement("DG", mesh.ufl_cell(), 1, dim=2)
6  W = FunctionSpace(mesh, MixedElement([Ne, Me, Qe]))
7
8  lamb, Sig = prob.add_var([R, W])
9  prob.add_obj_func([1, None])
10
11  (N, M, Q) = split(Sig)
12  T = as_matrix([[N[0], N[2]],
13                [N[2], N[1]],
14                [Q[0], Q[1]]])
15  M = to_mat(M)

```

482 where the different unknown fields $\boldsymbol{\Sigma} = (\mathbf{N}, \mathbf{M}, \mathbf{Q})$ have been defined and collected into a global vector.
 483 Equilibrium and continuity equations are then defined as in section 4.2 for continua by specifying the Lagrange
 484 multiplier function space and writing the weak form of the constraint:

```

1  V_f_eq = VectorFunctionSpace(mesh, "DG", 0, dim=3)
2  def force_equilibrium(u):
3      u_loc = dot(Ploc, u)
4      return [dot(u, f)*lamb*dx, dot(u_loc, divT(T))*dx]
5  prob.add_eq_constraint(V_f_eq, A=force_equilibrium)
6
7  V_m_eq = VectorFunctionSpace(mesh, "DG", 1, dim=2)
8  def moment_equilibrium(theta):
9      return [None, dot(theta, divT(M)+Q)*dx]
10 prob.add_eq_constraint(V_m_eq, A=moment_equilibrium)
11
12 V_f_jump = VectorFunctionSpace(mesh, "Discontinuous Lagrange Trace", 1, dim=3)
13 Tglob = dot(Ploc.T, T)
14 def force_continuity(v):
15     return [None, dot(avg(v), jump(Tglob, n_plan))*dS]
16 prob.add_eq_constraint(V_f_jump, A=force_continuity)
17

```

```

18 V_m_jump = VectorFunctionSpace(mesh, "Discontinuous Lagrange Trace", 2, dim=3)
19 Mglob = dot(Ploc_plane.T, M)
20 def moment_continuity(vtheta):
21     return [None, dot(avg(vtheta), cross(jump(Mglob, n_plan), avg(nu)))*dS]
22 prob.add_eq_constraint(V_m_jump, A=moment_continuity)

```

where the `Ploc` (resp. `Ploc_plane`) variable corresponds to a rotation matrix transforming fields expressed in the global $(\mathbf{e}_x, \mathbf{e}_y, \mathbf{e}_z)$ into the local $(\mathbf{a}_1, \mathbf{a}_2, \boldsymbol{\nu})$ (resp. $(\mathbf{a}_1, \mathbf{a}_2)$) frame. Note that we approximated the bending moment continuity equation by $[[\mathbf{M} \cdot \mathbf{n}] \times \hat{\boldsymbol{\nu}}]$ using an average normal vector $\hat{\boldsymbol{\nu}} = (\boldsymbol{\nu}^+ + \boldsymbol{\nu}^-)/2$.

If the previous snippets illustrate the efficiency of FEniCS high-level symbolic formulations for this kind of complex problem, the conic representation framework will also be extremely beneficial for formulating the shell strength criterion. Indeed, as discussed in length in [9], even for the simple case of a homogeneous von Mises thin shell, the strength condition expressed in terms of (\mathbf{N}, \mathbf{M}) stress-resultant becomes extremely complicated [30] so that simple SOC-representable approximations have been proposed in the past for the von Mises shell [58]. In [9], we proposed a general way of formulating an (\mathbf{N}, \mathbf{M}) shell strength criterion for a general multilayered shell through an up-scaling procedure. It is given by:

$$(\mathbf{N}, \mathbf{M}) \in G_{\text{shell}} \iff \begin{cases} \exists \boldsymbol{\sigma}(z) \in \mathcal{G}_{\text{ps}} \quad \forall z \in [-h/2; h/2] \text{ and s.t.} \\ \mathbf{N} = \int_{-h/2}^{h/2} \boldsymbol{\sigma}(z) \, dz \\ \mathbf{M} = \int_{-h/2}^{h/2} (-z) \boldsymbol{\sigma}(z) \, dz \end{cases} \quad (58)$$

where h is the shell thickness and \mathcal{G}_{ps} is the material local plane-stress criterion, which may potentially depend on coordinate z for a multilayered shell. To make formulation (58) usable in practice, the local plane-stress distribution $\boldsymbol{\sigma}(z)$ is replaced by a discrete set of plane-stress states $\boldsymbol{\sigma}_g = \boldsymbol{\sigma}(z_g)$ expressed at quadrature points z_g which are used to approximate the two integrals:

$$(\mathbf{N}, \mathbf{M}) \in G_{\text{shell}}^{\text{approx}} \iff \begin{cases} \exists \boldsymbol{\sigma}_g \in \mathcal{G}_{\text{ps}} \quad \forall g = 1, \dots, n_z \text{ and s.t.} \\ \mathbf{N} = \sum_{g=1}^{n_z} \omega_g \boldsymbol{\sigma}_g \\ \mathbf{M} = \sum_{g=1}^{n_z} (-z_g) \omega_g \boldsymbol{\sigma}_g \end{cases} \quad (59)$$

where ω_g are the corresponding quadrature weights of the n_z -points quadrature rule. As discussed in [9], the precise choice of the quadrature rule leads to different kinds of approximations to G_{shell} : e.g. an upper bound approximation is obtained with a trapezoidal quadrature rule, a Gauss-Legendre quadrature leads to an approximation with no lower or upper bound status, a rectangular rule will give a lower bound approximation. In the following, we choose the latter to be consistent with the lower bound status of the static approach.

From (59) it can readily be seen that if \mathcal{G}_{ps} is SOC-representable, so will be $G_{\text{shell}}^{\text{approx}}$. For instance, in the case of a plane-stress von Mises criterion of uniaxial strength σ_0 , it can be shown that:

$$\boldsymbol{\sigma} \in \mathcal{G}_{\text{ps}} \text{ von Mises} \iff \begin{cases} \boldsymbol{\sigma} = \mathbf{J} \bar{\mathbf{y}} \\ y_0 = \sigma_0 \\ \|\bar{\mathbf{y}}\| \leq y_0 \end{cases} \quad \text{where } \mathbf{J} = \begin{bmatrix} 1 & 1/\sqrt{3} & 0 \\ 0 & 2/\sqrt{3} & 0 \\ 0 & 0 & 1/\sqrt{3} \end{bmatrix} \quad (60)$$

in which the last constraint is a \mathcal{Q}_4 quadratic cone. Choosing a rectangular quadrature rule with $\omega_g = h/n_z$

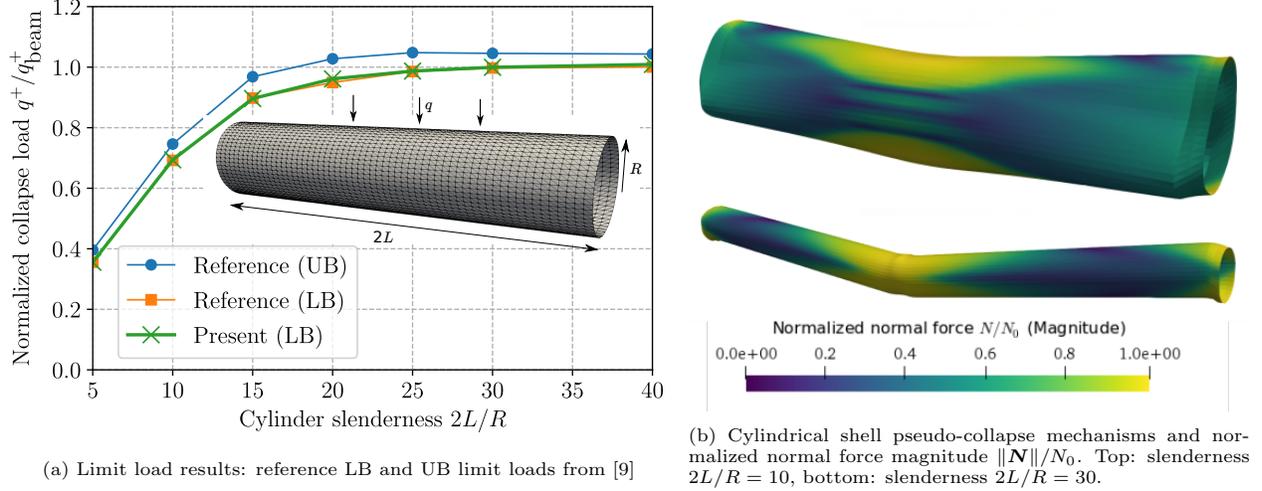

Figure 11: Cylindrical shell under self-weight

507 and $z_g = -\frac{h}{2} + \frac{h}{n_z}(g - \frac{1}{2})$ for $g = 1, \dots, n_z$, we therefore have:

$$(N, M) \in G_{\text{shell}}^{\text{approx}} \iff \begin{cases} \exists \mathbf{y}_g = (y_{0g}, \bar{\mathbf{y}}_g) \in \mathcal{Q}_A \quad \forall g = 1, \dots, n_z \text{ and s.t.} \\ y_{0g} = \sigma_0 \\ N = \sum_{g=1}^{n_z} \frac{h}{n_z} \mathbf{J} \bar{\mathbf{y}}_g \\ M = \sum_{g=1}^{n_z} (-z_g) \frac{h}{n_z} \mathbf{J} \bar{\mathbf{y}}_g \end{cases} \quad (61)$$

508 which obviously fits format (22). Let us finally remark that the approximation will converge to the shell
 509 criterion G_{shell} when increasing n_z . In the following we took $n_z = 6$.

510 As an illustrative application, we consider the problem of a cylindrical shell of length $2L$, radius R
 511 and thickness $h = 0.01R$, clamped at both extremities and loaded by a self-weight uniform vertical loading
 512 $\mathbf{f} = -q\mathbf{e}_z$ (see Figure 11a). The shape of the collapse mechanism varies depending on the cylinder slenderness
 513 $2L/R$. For sufficiently long cylinders, the computed limit load q^+ is well described by the one obtained when

514 representing the cylinder as a 1D beam $q_{\text{beam}}^+ = \frac{32}{\pi} N_0 \left(\frac{R}{2L}\right)^2$ with $N_0 = \sigma_0 h$ being the membrane uniaxial

515 strength. The obtained limit loads agree very well with the lower bound result of [9]. Having access to the
 516 Lagrange multiplier \mathbf{u} , we reconstructed a pseudo-collapse mechanism by performing a projection of \mathbf{u} on a
 517 continuous \mathbb{P}^1 space. The obtained deformations have been represented in Figure 11b along with the normal
 518 force magnitude distribution. It can be seen that the mechanisms agree well with those obtained from an
 519 upper bound kinematic approach in [9], with a beam-like mechanism involving plastic hinges at the clamped
 520 supports and mid-span for the case $2L/R = 30$.

521 7. Generalized continua

522 In this last section, we further illustrate the proposed framework on two generalized continuum models,
 523 namely a strain gradient and a Cosserat continuum. We would like to point out that the numerical imple-
 524 mentation of limit analysis for these kinds of model is almost non-existent whereas we will show that it can
 525 now be easily formulated with the proposed framework.

526 7.1. Strain-gradient material

527 In this subsection, we consider the extension of limit analysis to strain gradient materials. We do not
 528 attempt at providing physical justifications for using this kind of model but let us just mention that it can,

529 for instance, be obtained when considering the elastically rigid version of a strain-gradient plasticity model.
 530 We therefore consider the following strain-gradient generalization of the kinematic limit analysis theorem:

$$\begin{aligned} \inf_{\mathbf{u} \in \mathcal{V}_h} \quad & \int_{\Omega} \pi_{G_{SG}}((\nabla^s \mathbf{u}, \nabla^2 \mathbf{u})) \, dx \\ \text{s.t.} \quad & \int_{\Omega} \mathbf{f} \cdot \mathbf{u} \, dx + \int_{\partial\Omega_T} \mathbf{t} \cdot \mathbf{u} \, dS = 1 \end{aligned} \quad (62)$$

531 where we considered only classical loadings (body forces or surface tractions) and where the strain operator
 532 $\mathbf{D}\mathbf{u} = (\nabla^s \mathbf{u}, \nabla^2 \mathbf{u})$ now includes both the first and second displacement gradient of \mathbf{u} with $(\nabla^2 \mathbf{u})_{ijk} = u_{i,jk}$.
 533 We do not consider here the equivalent static formulation but let us just point out that the generalized stress
 534 $\boldsymbol{\Sigma} = (\boldsymbol{\sigma}, \boldsymbol{\tau})$ includes both the standard Cauchy stress $\boldsymbol{\sigma}$ and the third-rank couple stress tensor $\boldsymbol{\tau} = (\tau_{ijk})$
 535 which is associated by duality with the second gradient $\nabla^2 \mathbf{u}$. The generalized strength criterion therefore
 536 depends both on $\boldsymbol{\sigma}$ and $\boldsymbol{\tau}$. For simplicity, we will consider the following extended von Mises criterion:

$$(\boldsymbol{\sigma}, \boldsymbol{\tau}) \in G_{SG} \Leftrightarrow \sqrt{\frac{1}{2}(\mathbf{s} : \mathbf{s} + \ell^{-2} \boldsymbol{\tau}^T : \boldsymbol{\tau})} \leq k \quad (63)$$

537 where $\mathbf{s} = \text{dev } \boldsymbol{\sigma}$, $\boldsymbol{\tau}^T : \boldsymbol{\tau} = \tau_{ijk} \tau_{ijk}$ and ℓ is an internal length scale. The associated support function is:

$$\pi_{G_{SG}}((\mathbf{d}, \boldsymbol{\eta})) = \sup_{(\boldsymbol{\sigma}, \boldsymbol{\tau}) \in G_{SG}} \{ \boldsymbol{\sigma} : \mathbf{d} + \boldsymbol{\tau}^T : \boldsymbol{\eta} \} = \begin{cases} k \sqrt{2(\mathbf{d} : \mathbf{d} + \ell^2 \boldsymbol{\eta}^T : \boldsymbol{\eta})} & \text{if } \text{tr } \mathbf{d} = 0 \\ +\infty & \text{otherwise} \end{cases} \quad (64)$$

538 where $\mathbf{d} = \nabla^s \mathbf{u}$ and $\boldsymbol{\eta} = \nabla^2 \mathbf{u}$.

Restricting to a plane strain situation, one has $\eta_{ij3} = \eta_{i3j} = \eta_{3ij} = 0$ and:

$$\begin{aligned} \eta_{111} &= u_{1,11} & \eta_{211} &= u_{2,11} \\ \eta_{122} &= u_{1,22} & \eta_{222} &= u_{2,22} \\ \eta_{112} &= \eta_{121} = u_{1,12} & \eta_{212} &= \eta_{221} = u_{2,12} \end{aligned} \quad (65)$$

539 Introducing $\mathbf{D} = (d_{11}, d_{22}, \sqrt{2}d_{12}, \ell\eta_{111}, \ell\eta_{122}, \sqrt{2}\ell\eta_{112}, \ell\eta_{211}, \ell\eta_{222}, \sqrt{2}\ell\eta_{212})$, one has $\mathbf{D}^T \mathbf{D} = \mathbf{d} : \mathbf{d} + \ell^2 \boldsymbol{\eta}^T : \boldsymbol{\eta}$
 540 so that $\pi_{G_{SG}}((\mathbf{d}, \boldsymbol{\eta})) = k \sqrt{2} \|\mathbf{D}\|_2$. Since $\pi_{G_{SG}}$ involves a L_2 -norm on a 9-dimensional vector, it can be
 541 represented using a 10-dimensional quadratic cone \mathcal{Q}_{10} (see [5]).

542 As regards the finite-element discretization, we choose a \mathbb{P}^2 -Lagrange interpolation for \mathbf{u} . In formulation
 543 (62), it is implicitly assumed that both \mathbf{u} and $\nabla \mathbf{u}$ are continuous. The latter condition will not be achieved
 544 easily by a standard FE discretization so that we supplement (62) by a discontinuity term for $\partial_n \mathbf{u} = \nabla \mathbf{u} \cdot \mathbf{n}$,
 545 similarly to thin plates:

$$\begin{aligned} \inf_{\mathbf{u} \in \mathcal{V}_h} \quad & \int_{\Omega} \pi_{G_{SG}}((\nabla^s \mathbf{u}, \nabla^2 \mathbf{u})) \, dx + \int_{\Gamma} \pi_{G_{SG}}((0, [\partial_n \mathbf{u}] \otimes \mathbf{n} \otimes \mathbf{n})) \, dS \\ \text{s.t.} \quad & \int_{\Omega} \mathbf{f} \cdot \mathbf{u} \, dx + \int_{\partial\Omega_T} \mathbf{t} \cdot \mathbf{u} \, dS = 1 \end{aligned} \quad (66)$$

546 with $\pi_{G_{SG}}((0, \partial_n \mathbf{u} \otimes \mathbf{n} \otimes \mathbf{n})) = k \sqrt{2} \ell \|[\partial_n \mathbf{u}]\|_2$ for (64). Again, this can be easily implemented in very few
 547 lines of code, regarding the problem complexity:

```

1  prob = MosekProblem("Strain gradient limit analysis")
2  u = prob.add_var(V, bc=bc)
3
4  D = as_vector([u[0].dx(0), u[1].dx(1), (u[0].dx(1)+u[1].dx(0))/sqrt(2),
5                1*u[0].dx(0).dx(0), 1*u[0].dx(1).dx(1), sqrt(2)*1*u[0].dx(0).dx(1),
6                1*u[1].dx(0).dx(0), 1*u[1].dx(1).dx(1), sqrt(2)*1*u[1].dx(0).dx(1)])
7  pi = L2Norm(D, quadrature_scheme="vertex")
8  prob.add_convex_term(k*sqrt(2)*pi)
9
10 isochoric = EqualityConstraint(div(u), quadrature_scheme="vertex")
11 prob.add_convex_term(isochoric)
12

```

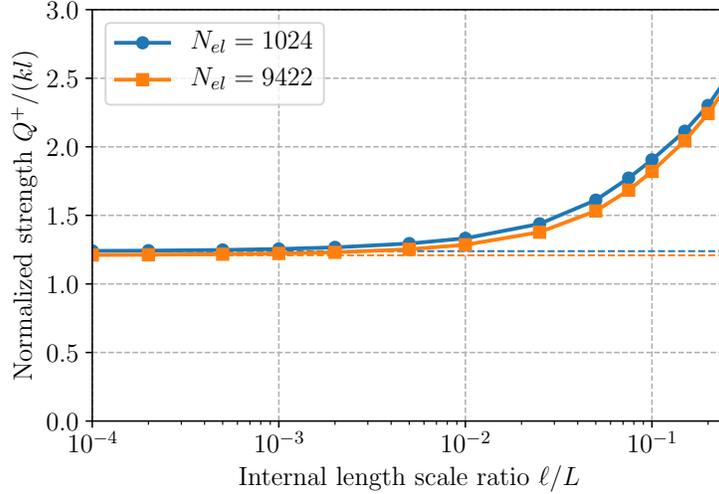

Figure 12: Evolution of the normalized uniaxial strength for the strain-gradient perforated traction as function of the internal length scale ℓ/L for two mesh sizes (dashed lines correspond to standard continuum limit analysis results $\ell = 0$).

```

13  n = FacetNormal(mesh)
14  pi_d = L2Norm([jump(k*sqrt(2)*l*grad(u), n)], on_facet=True)
15  prob.add_convex_term(pi_d)
16
17  prob.optimize()

```

As an illustrative application, we consider a rectangular domain of dimensions $L \times 1.5L$ perforated at its center by a circular hole of radius $R = 0.2L$. The bottom boundary is fully clamped and the top one is displaced vertically $\mathbf{u} = (0, U)$. No other loading is applied and the computed objective value of (66) will be Q^+U where $Q = \int_{y=H} \sigma_{yy} dS$ is the resultant force on the top boundary. The evolution of the normalized uniaxial strength $Q^+/(kL)$ is plotted for various values of the internal length parameter ℓ/L in Figure 12 for two different mesh sizes. As expected, the plate apparent strength is size-dependent and exhibits a strengthening behaviour for larger values of ℓ or, equivalently, smaller sample size L . The standard continuum limit analysis results (dashed lines) are retrieved when $\ell/L \rightarrow 0$. Collapse mechanisms along with dissipation fields π_{SG} are represented in Figure 13. Broadening of the plastic dissipation slip zones can clearly be observed for increasing values of ℓ/L .

7.2. A Cosserat-continuum model for jointed rocks

We further illustrate the ability of the proposed framework to tackle generalized continua by considering a Cosserat (or micropolar continuum) model for jointed rocks, initially proposed in [20]. The governing equations of the model, in plane strain conditions, involve a non-symmetric stress tensor $\boldsymbol{\Sigma} = \begin{bmatrix} \Sigma_{11} & \Sigma_{12} \\ \Sigma_{21} & \Sigma_{22} \end{bmatrix}$ and a couple stress vector $\mathbf{H} = (H_1, H_2)$ both expressed in the local reference frame $(\mathbf{e}_1, \mathbf{e}_2)$ of the jointed rock mass (see Figure 14). The corresponding equilibrium equations read as:

$$\operatorname{div} \boldsymbol{\Sigma} + \mathbf{f} = 0 \quad (67)$$

$$\operatorname{div} \mathbf{H} + \Sigma_{21} - \Sigma_{12} = 0 \quad (68)$$

the corresponding weak form obtained from the virtual work principle being:

$$\int_{\Omega} \left(\boldsymbol{\Sigma}^T : (\nabla \mathbf{u} - \operatorname{skew} \boldsymbol{\omega}) + \mathbf{H} \cdot \nabla \boldsymbol{\omega} \right) dx = \int_{\Omega} \mathbf{f} \cdot \mathbf{u} dx \quad (69)$$

for any continuous test function \mathbf{u} and $\boldsymbol{\omega}$ with $\operatorname{skew} \boldsymbol{\omega} = \boldsymbol{\omega}(\mathbf{e}_2 \otimes \mathbf{e}_1 - \mathbf{e}_1 \otimes \mathbf{e}_2)$ and where we considered only body forces as loading parameters.

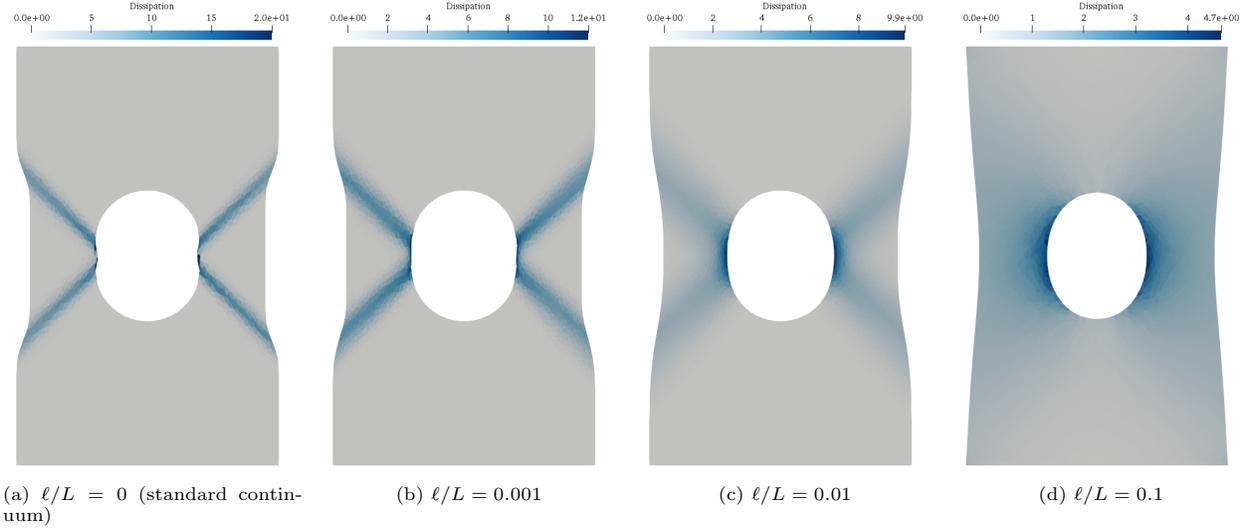

Figure 13: Collapse mechanism and plastic dissipation as function of internal length scale ratio ℓ/L

562 As regards strength properties, the rock mass is assumed to obey a Mohr-Coulomb criterion of cohesion c_m
 563 and friction angle ϕ_m . The joints are represented as an orthogonal array, spaced by a length ℓ and making an
 564 angle θ with the horizontal axis. They are assumed to also obey a Mohr-Coulomb condition with parameters
 565 (c_j, ϕ_j) . The generalized strength condition for a jointed rock mass modelled as a Cosserat continuum is
 566 expressed as [20]:

$$(\boldsymbol{\Sigma}, \mathbf{H}) \in G_{\text{Cosserat}} \iff \begin{cases} \Sigma_{11} \tan \phi_j + |\Sigma_{21}| \leq c_j \\ \Sigma_{22} \tan \phi_j + |\Sigma_{12}| \leq c_j \\ \frac{\ell}{2} \Sigma_{11} + |H_1| \leq \frac{\ell}{2} \frac{c_j}{\tan \phi_j} \\ \frac{\ell}{2} \Sigma_{22} + |H_2| \leq \frac{\ell}{2} \frac{c_j}{\tan \phi_j} \\ |H_1| \leq \frac{\ell}{2} \frac{c_j}{\cos \phi_j} \\ |H_2| \leq \frac{\ell}{2} \frac{c_j}{\cos \phi_j} \\ \text{sym } \boldsymbol{\Sigma} \in G_{\text{MC,2D}}(c_m, \phi_m) \end{cases} \quad (70)$$

567 where the last condition expresses the rock mass Mohr-Coulomb criterion on $\text{sym } \boldsymbol{\Sigma} = (\boldsymbol{\Sigma} + \boldsymbol{\Sigma}^T)/2$ and
 568 where all other conditions involve the joints resistance. Let us point out that the case $\ell = 0$ induces $H_i = 0$
 569 and thus $\boldsymbol{\Sigma} = \boldsymbol{\Sigma}^T$ due to (68), one therefore retrieves a Cauchy model with a strength criterion described
 570 by the first, second and last conditions of (70). Finally, G_{Cosserat} involves only linear inequality constraints
 571 in addition to the Mohr-Coulomb criterion $G_{\text{MC,2D}}$. It is, therefore, SOC-representable, the part involving
 572 joints only being linear-representable.

573
 574 A mixed approach for this model has been implemented in the spirit of (41) which avoids the need to
 575 compute the support function expression associated with (70). Continuous \mathbb{P}^2 (resp. \mathbb{P}^1) Lagrange elements
 576 have been used for \mathbf{u} (resp. $\boldsymbol{\omega}$) and discontinuous \mathbb{P}_d^1 -Lagrange elements for both $\boldsymbol{\Sigma}$ and \mathbf{H} . The strength
 577 conditions have been imposed at the vertices of each element. We considered the stability problem of an
 578 excavation of height H , making a 25° angle with the vertical and subjected to its self-weight of intensity γ .
 579 The problem amounts to find the maximum value of the non-dimensional stability factor $K^+ = \left(\frac{\gamma H}{c_m}\right)^+$.

580 For numerical applications, we took $c_j = 0.5c_m$, $\phi_j = 20^\circ$, $\phi_m = 40^\circ$, $\theta = 10^\circ$ and varied the joint spacing
 581 ℓ . The evolution of the stability factor estimates as a function of ℓ/H has been represented in Figure 15

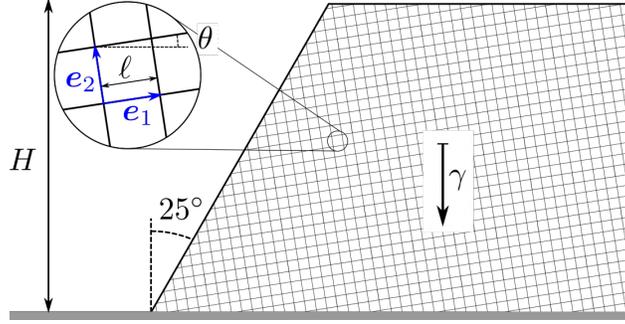

Figure 14: Stability of a jointed rock excavation

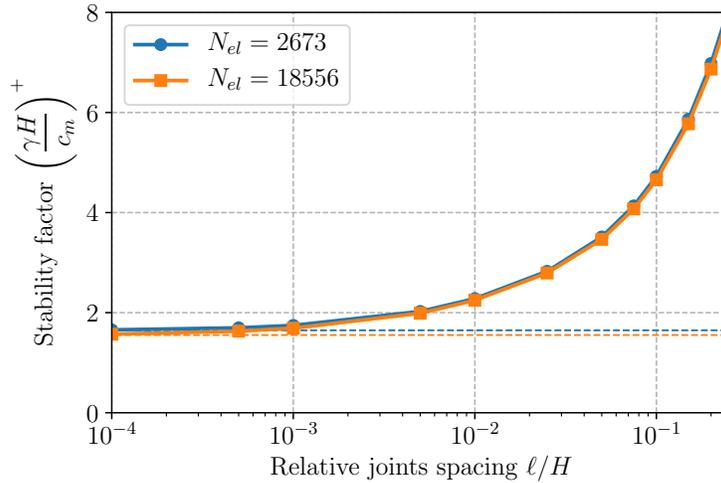

Figure 15: Evolution of the stability factor as function of the joints spacing ℓ/H for two mesh sizes (dashed lines correspond to standard continuum limit analysis results $\ell = 0$).

582 for two different mesh sizes. As for the strain gradient model, strengthening is observed for increasing ℓ/H
583 ratios. Interestingly, size-effects are much stronger for this problem than those of Figure 12. The obtained
584 value in the standard Cauchy ($\ell = 0$) case is quite close to the analytical upper bound of $K^+ \leq 1.47$ derived
585 for the same problem in [20]. Finally, collapse mechanisms and a measure of the pure Cosserat contribution
586 $(\Sigma_{21} - \Sigma_{12})(u_{2,1} - u_{1,2} - \omega) + \mathbf{H} \cdot \nabla \omega$ to the total dissipation have been represented in Figure 16. It can be
587 observed that the shape of the collapse mechanism and the location of "shearing" zones involving Cosserat
588 effects is quite dependent on the joint spacing. For $\ell = 0$, a triangular sliding block with a concentrated slip
589 zone is obtained, approximately corresponding to the merging of the two slip bands of Figure 16a.

590 8. Conclusions

591 This paper proposed a way to easily formulate and solve limit analysis problems by taking advantage of
592 three essential ingredients:

- 593 • the FEniCS finite element library with its high-level domain specific language and large choice of
594 finite-element interpolations;
- 595 • the representation of limit analysis criteria and associated support functions in a conic programming
596 format, including the use of recently available power and exponential cones;

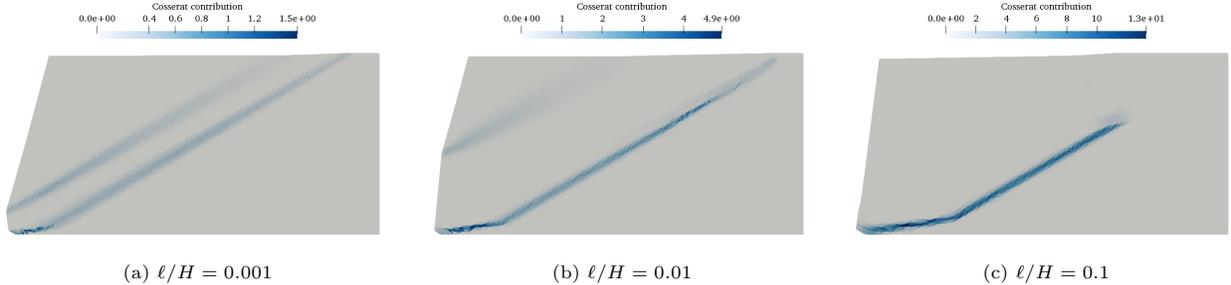

Figure 16: Collapse mechanism of the jointed rock excavation and pure Cosserat contribution to the total dissipation

- the resolution of the corresponding conic optimization problems by a dedicated and efficient interior-point solver implemented in the `Mosek` software package.

The first two ingredients offer an extremely large versatility in the problem definition, giving access to an extremely large range of applications. In particular, various finite-element interpolations can be easily defined, giving access to traditional continuous displacement-based upper-bound formulations but also their discontinuous counterpart through Discontinuous Galerkin function spaces. Equilibrium lower-bound elements are therefore also accessible through such spaces as well as mixed formulations through different choices of quadrature rules. We also showed that plates and shells problems could also be discretized without effort. The conic representation format (22) offers a unified way of defining strength conditions and associated support functions for different mechanical models, ranging from classical 2D/3D continuum mechanics to plate bending criteria including potential shear conditions, shell criteria with membrane/bending interaction or even generalized continua such as Cosserat or strain gradient models. If the conic representation format is large enough to encompass many strength criteria, it is also sufficiently disciplined to yield optimization problems of the conic programming class for which dedicated solvers like `Mosek` have been designed. `Mosek` is indeed known to be a state-of-the-art optimizer for this class of problems and therefore offers efficiency and robustness of the solution procedure.

Obviously, the present work could still improve upon some aspects, in particular regarding computational efficiency. For instance, many additional auxiliary variables are usually introduced when complying with the conic programming format. Some of them may be handled and eliminated by `Mosek` during its pre-processing phase, although this is not entirely clear since it is used as a black-box. Devising an interior-point solver specific to limit analysis problems can take advantage of the problem structure and may be more efficient. Besides, there are two points which prevent solving extremely large-scale 3D problems. The first one is related to the use of direct solvers in the interior-point inner iterations which requires large memory capacities for 3D problems. The use of iterative solvers is still an active research topic due to the difficulty of efficiently preconditioning the interior-point linear systems. The second one concerns the need to solve SDP problems when SDP-representable criteria like Mohr-Coulomb, Tresca or Rankine are used in 3D. Even though interior-point solvers efficiency has greatly improved for SDP problems over the last decade, it is still more difficult to solve than an SOCP problem of similar size. Improving even more their efficiency or finding alternate strategies would be a great benefit for such 3D problems.

If mathematical programming (and more particularly conic programming) tools for solving limit analysis has now emerged as the state-of-the-art method, some extensions have already been proposed in the literature to apply them also to closely related problems. One can mention, for instance, elastoplasticity [38, 37], viscoplasticity for yield stress fluids [11, 4], contact in granular materials [36, 70], limit analysis-based topology optimization [32, 26], etc. The present framework is sufficiently general to also extend to these related problems, see for instance the application to viscoplastic fluids in [5]. Other situations appear however more difficult to include such as non-associative behaviours or geometrical non-linearities since such problems cannot be formulated as convex optimization problems anymore. Nonetheless, some works have already proposed some iterative strategies for tackling non-associativity [25, 35, 57] or geometrical changes using sequential limit analysis [69]. These strategies rely on an iterative resolution of classical associated limit analysis problems and could be implemented with the proposed framework without any difficulty.
